Key Points:

- The Hunga Tonga-Hunga Ha'apai eruption of 15 January 2022, lofted material above 30 km to record-breaking heights of ~55 km.

- Our stereo-winds code retrieved height and motion vectors from GOES-17 and Himawari-8 every 10 minutes immediately after the event.

- Radio Occultation bending angles confirm plume altitudes.

Abstract

Stereo methods using GOES-17 and Himawari-8 applied to the Hunga Tonga-Hunga Ha'apai volcanic plume on 15 January 2022 show overshooting tops reaching 50-55 km altitude, a record in the satellite era. Plume height is important to understand dispersal and transport in the stratosphere and climate impacts. Stereo methods, using geostationary satellite pairs, offer the ability to accurately capture the evolution of plume top morphology quasi-continuously over long periods. Manual photogrammetry estimates plume height during the most dynamic early phase of the eruption and a fully automated algorithm retrieves both plume height and advection every 10 minutes during a more frequently sampled and stable phase beginning three hours after the eruption. Stereo heights are confirmed with Global Navigation Satellite System Radio Occultation (GNSS-RO) bending angles, showing that most of the plume was lofted 30–40 km into the atmosphere. Cold bubbles are observed in the stratosphere with brightness temperature of ~173K.

Plain Language Summary

The Hunga Tonga-Hunga Ha'apai volcano in the South Pacific erupted violently on January 15, 2022. A volcanic plume from the eruption was lofted into the stratosphere to altitudes that are unprecedented in the era of satellite observations. We observed the highest part of the plume at 55 km and tracked the motion of the plume in 3D in the vicinity of the volcano for a seven-hour period, every 10 minutes, using imagery from the geostationary GOES-17 and Himawari-8 satellites that are positioned at different locations on the equator. The apparent shift in the plume as seen from two different vantage points contains information about the plume height and the apparent movement of the plume as it is repeatedly observed by one satellite contains information about the plume velocity. We confirmed our height observations using radio occultation measurements that NOAA uses to profile the atmosphere. Radio waves are normally bent as they pass through the atmosphere from satellite to satellite, nearly grazing the Earth's surface, but when radio waves pass through the volcanic plume, there is an anomalously large change in bending angle.

1 Introduction

The Hunga Tonga-Hunga Ha'apai eruptions of January 2022 culminated in a dramatic event on 15 January 2022. The plume from this underwater eruption was captured in imagery from the geostationary GOES-17 and Himawari-8 satellites beginning just after 04:00Z. Applying stereo methods to this imagery, we show that the 15 January 2022 eruption lofted a volcanic plume well above the tropopause and into the stratosphere, with the highest overshooting tops reaching altitudes of 50–55 km, a record in the satellite era. Determining the height of volcanic plumes has an important implication for their dispersion and transport in the atmosphere as well as their lifetime impacts on Earth's climate. Although other observational techniques exist to estimate volcanic plume heights, including the temperature method, LiDAR (e.g., CALIOP), and UV limb sounding (e.g., OMPS), only stereo methods using geostationary satellite pairs offer the ability to accurately capture the evolution of plume top morphology quasi-continuously over long periods. We use manual photogrammetry to estimate plume height during the most dynamic early phase of the eruption and a fully automated algorithm to retrieve both plume height and advection every 10 minutes during a more frequently sampled and stable phase beginning three hours after the eruption. Global Navigation Satellite System Radio

63 Occultation (GNSS-RO) bending angles similarly show that the bulk of the plume was lofted 30–
64 40 km into the atmosphere.

2 Materials and Methods

66 We rely on stereo methods previously developed at NASA for tracking wind tracers from
67 multiple satellites ("stereo winds"). These tools have already been applied to stereo observations
68 from Himawari-8 and MODIS of the 2019 eruption of Raikoke (Horváth et al., 2021a and
69 2021b). The stereo-winds code for a geostationary pair is fully described in Carr et al. (2020). It
70 offers the ability to retrieve both the height and the motion of a volcanic plume automatically and
71 nearly continuously until the eruption dies down and the plume becomes too tenuous to track
72 effectively. A similar approach has been applied to the study of an eruption of Mt. Etna in 2013
73 using a pair of Meteosat satellites (Merucci et al., 2016).

74 We use geostationary satellite imagery from GOES-17 nominally stationed at 137.2°W
75 and Himawari-8 nominally stationed at 140.7°E. Both satellites have nearly identical 16-channel
76 imagers and capture the Earth's Full Disk (FD) every 10 minutes. Both imagers have similar
77 capabilities to acquire smaller sectors with shorter refresh times. In particular, GOES can acquire
78 an approximately $1000{\times}1000$ km^2 Mesoscale (MESO) scene every 1 minute. NOAA centered a
79 MESO scene over the eruption at 07:05Z to begin covering the volcano every minute. Before
80 07:05Z, the volcano was only covered in the FD scenes repeating every 10 minutes. Stereo-
81 winds feature tracking works better when the time between scene repetitions is shorter. At the
82 beginning of this eruption, as the radius of the plume top expanded at a mean radial speed of ~50
83 m s^{-1} from ~20 km at 04:10Z to ~55 km at 04:20Z and to ~80 km at 04:30Z, features that
84 otherwise could be tracked morphed quickly in the billowing and rapidly expanding plume. This
85 made automated feature tracking more difficult using the 10-minute GOES-17 FD scenes.
86 Therefore, we focused our use of the stereo-winds code on GOES-17 MESO scenes paired with a
87 single near-simultaneous Himawari FD and used manual photogrammetry (stereo and shadow
88 analysis) with FD pairs before 07:05Z. For example, the Himawari FD beginning at 07:00Z,
89 starts above the North Pole and progresses towards the south, reaching the volcano around
90 07:06Z; therefore, we pair GOES MESO scenes at 07:05Z, 07:06Z, and 07:07Z with the single
91 07:00Z Himawari FD scene. This pattern repeats every 10 minutes. The sun has already set at
92 the volcanic site by 07:00Z, so we use the long-wave Band 14 (B14) with a center wavelength at
93 11.2 µm and spatial resolution of 2 km for both satellites.

94 Simultaneous stereo pairs are not required by the stereo-winds code as pixel acquisition
95 times are used in the retrieval model. In our case, the 07:06Z GOES-17 MESO and the 07:00Z
96 Himawari FD differ from exact simultaneity by either ~10 s, ~40 s, or ~70 s across the mesoscale
97 domain depending on which of the three 30-s swaths of the Himawari FD that cover the
98 mesoscale domain contain the pixel. The apparent displacement of a feature between images
99 represents a combination of motion and geometric parallax that the model separates knowing the
100 pixel times.

101 Our manual photogrammetry relies on the highest resolution (0.5 km) GOES and
102 Himawari red band (0.64 µm) FD pairs with a typical non-simultaneity of ~30 s in each 10-
103 minute slot. Prata and Grant (2001) and Horváth et al. (2021a) give a detailed description of the
104 method. In short, the height of a feature visually matched in the two images is determined from
105 the ellipsoid-projected parallax between the match points and the corresponding satellite
106 view/azimuth angles. The method can also be applied to apparent shadows observed in a single

107   image. The second satellite view is effectively replaced by the solar-projected location of the
108   feature, i.e., the shadow terminus. Note that the method can estimate the height but not the
109   motion of a feature. The shadow variant has the advantage of only requiring a single image.
110   Still, sampling is limited to shadowed areas, and it can be challenging to pinpoint the exact
111   location of the shadow terminus due to the blurring effect of a penumbra.
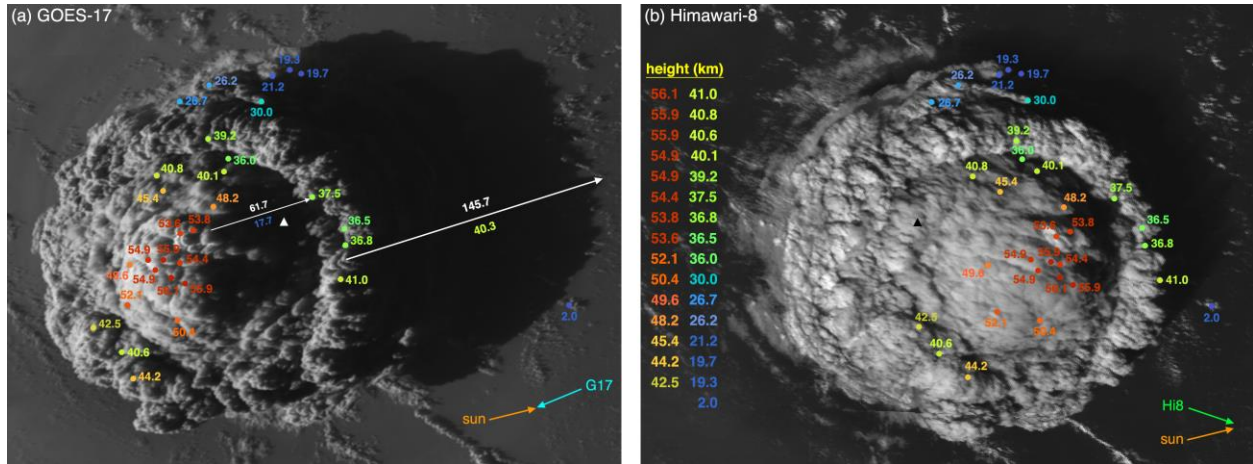

112   Manual feature matching between two satellite images of the plume is relatively
113   straightforward; however, the horizontal and vertical motion of the feature introduces a height
114   error due to any non-simultaneity between views. In our case, the GOES-17 and Himawari-8
115   view zenith/azimuth angles are around 50º/66º and 55º/-71º, respectively. This stereo geometry
116   leads to a parallax almost precisely in the east-west direction, and a height error of ~0.4 km for
117   every 1 km parallax error (see Eq. 8 in Horváth et al., 2021a)—the corresponding height error
118   sensitivity for our shadow geometry is ~0.3 km per 1 km parallax. In the early phases of the
119   eruption, the velocity of the fastest moving plume element is ~50 m s^{-1} in both the horizontal and
120   vertical directions. During the 30 s between the satellite views, this results in a ~1.5 km
121   horizontal movement and a ~1.5 km vertical rise, the latter of which translates to a ~3.7 km
122   parallax increase. In the worst case, when these motion parallax errors add up, the total parallax
123   error is ~5.2 km, amounting to a ~2 km height overestimation. Vertical velocity can be negative
124   (but smaller in magnitude) when overshooting tops collapse. There can also be partial
125   cancellation between the motion parallax errors, depending on the direction of the horizontal
126   velocity. Therefore, a ±2 km height uncertainty is expected for the most dynamic plume features
127   (although overestimation is more likely than underestimation), which is acceptable considering
128   the extreme heights encountered. Both manual photogrammetry and stereo-winds methods are
129   most accurate when the motion is predominantly perpendicular to the local vertical and stereo
130   pairings are nearly simultaneous.

131   **3 Results**

132   3.1 Manual Photogrammetry

133   Figure 1 shows the maximum height estimates found at 04:30Z. The plume resembled a
134   stack of pancakes with several identifiable layers, capped by a large central dome (see the
135   contrast-enhanced Supplementary Exhibit S1). Heights were calculated for thirty plume
136   retrievals and one low-level cloud at 2 km altitude serving as a reference. The stereo retrievals
137   indicate layers at 20–21 km, 26–27 km, and the massive topmost ring of ~80 km radius at 38–40
138   km. There are significant km-scale variations within this rugged topmost ring, demonstrating the
139   sheer dynamism of the explosive rise. Most remarkably, the central dome reached an altitude of
140   ~55 km. The retrievals show a systematic increase in height as sampling ascends from the base
141   to the dome's peak. A rough estimate of peak height from applying the side view method of
142   Horváth et al. (2021a) to the corresponding GEO-KOMPSAT-2A image is in Supplementary
143   Exhibit S2. The GOES-17 view was favorable for applying the shadow method and is unaffected
144   by motion effects. The long white arrow marks the apparent shadow of a local peak in the
145   topmost ring, cast on the ocean surface. For a solar zenith/azimuth angle of 68º/-108º, the 145.7
146   km shadow length corresponds to a plume edge height of ~40 km, in good agreement with the
147   nearby GOES-17–Himawari-8 stereo estimates. The shorter white arrow indicates the shadow of
148   a dome feature cast on the ring. This 61.7 km long shadow corresponds to an ~18 km height
149   differential relative to the ~38 km altitude of the ring feature at the shadow terminus, consistent

150 with a peak dome altitude of ~55 km within the expected tolerance of ±2 km. Shadow-based
151 plume height estimates for the 04:50–05:00Z time slots are also in Supplementary Exhibit S3.

152

Figure 1. Image of the plume on 15 January 2022 at 04:30Z from (a) GOES-17 and (b)
Himawari-8. Colored dots mark manual stereo height estimates (in km), and the triangle shows
the volcano's location. The white arrows in panel (a) depict the shadow of a plume edge feature
and a dome feature, with the shadow length and the derived height given above/below the arrow.
Arrows in the lower right of each panel indicate the sun-to-pixel and satellite-to-pixel azimuths.

155
156
157

158 3.2 Automated Stereo-Winds Method

159 The stereo-winds method was applied after 07:05Z when NOAA placed the GOES-17
160 MESO1 scene on the volcano. The 1-minute cadence of the MESO scenes is nearly ideal as it
161 allows enough time for motion to be observed but leaves feature shapes sufficiently invariant to
162 be accurately tracked with subpixel precision. Figure 2a shows the jointly retrieved stereo
163 heights, and advection vectors for 08:06Z (uses GOES-17 MESO scenes at 08:05Z, 08:06Z,
164 08:07Z) paired with the Himawari 08:00Z FD. Smaller tracking templates allow for a higher
165 resolution characterization of the plume geometry and dynamics, but this must be balanced
166 against tracking accuracy. We selected 16x16 pixel templates (32 km feature spatial resolution)
167 and oversampled the scene 4:1 (8 km sampling). A lofted stratospheric plume mostly above 30
168 km is seen over a lower cold umbrella at ~18 km near the tropopause. The expansion and
169 westward drift of the plume is evident from the advection vectors. Accompanying temperature
170 assignments have been made according to the Effective Blackbody Temperature (EBBT) of the
171 tracking templates taken from the 08:06Z MESO scene. Templates lower than 22 km (cold
172 umbrella and troposphere) are presumed to be cold targets over warmer backgrounds and are
173 assigned the mean temperature of the 20% coldest pixels. Templates 22 km and above are
174 expected to be warmer than the cold umbrella and are assigned the mean temperature of the 20%
175 warmest pixels because of the negative stratospheric lapse rate. However, where the plume
176 becomes optically thin (effectively semi-transparent) near its edges, heat from the troposphere
177 below makes the templates appear warmer than expected in the stratosphere up to 35 km (> 240
178 K). In such cases, a colder pattern is being tracked over a warm background, and the 20%
179 coldest pixels are averaged to be more representative of the plume temperature. This approach to

180   temperature assignment is similar in concept to that proposed by Borde, et al. (2014) where the
181   assignment is being made based on the pixels that are most important for feature tracking.

182   ERA5 and GNSS-RO temperature profiles are provided in Figure 2b for context, which
183   may not be entirely accurate in the presence of volcanic ash; however, the EBBTs of both the
184   plume and tropospheric clouds broadly follow and cluster near both profiles. Deviations from
185   the profiles are indicative of challenges with temperature-based height assignment, which in
186   general is complicated by inversions, semitransparency, undercooling, temperature assignment
187   uncertainty, and targets with emissivity less than one. Additional confidence in the stereo
188   retrievals is gained by noting that the field of marine stratocumulus (Sc) clouds in the SW
189   quadrant of the mesoscale domain has stereo heights between 500 m and 1.5 km. These are
190   within expectations for such clouds and match well with the NOAA temperature-based cloud top
191   height product for this scene.

192

Figure 2. Panel (a) shows the jointly retrieved heights and horizontal advection vectors at their
parallax corrected locations centered on the volcano (20.536°S, 175.382°W). The vector scale at
the upper right indicates a 50 m s^{-1} wind in each direction. Panel (b) shows the assigned
temperatures for each retrieval and the associated advection speed. Temperature profiles from
ERA5 at 08:00Z and COSMIC-2 RO at 07:11Z have been added for context.

198   The 08:06Z scene was selected for Figure 2 as an interesting case because it clearly
199   shows an eruption of volcanic ash overshooting the plume top centered over the marked volcanic
200   site (Global Volcanism Program, 2013). All stereo-winds product files are found in the
201   supplement, along with animations of the IR imagery, height-coded advection fields, and height
202   versus temperature profiles for the complete set (Exhibits S4ff). At 08:41Z, an overshooting
203   plume core reached the upper stratosphere with an EBBT of ~173K, significantly colder than the
204   surrounding stratospheric plume. This cold bubble has an EBBT ~15K colder than the lower
205   umbrella near the tropopause, which can be explained by adiabatic cooling during plume
206   convection (Woods and Self, 1992). Atmospheric gravity waves are also evident in the
207   animations.

208   The evolution of the mesoscale plume height statistics from 07:06Z to 13:46Z for 15
209   January 2022 is detailed in Figure 3. At each time, this density plot presents the distribution of
210   retrieved heights. Optically thick parts of the plume at a higher altitude can block the view of
211   elements underneath, which explains the lower number density in the cold umbrella when the
212   upper-level plume has a higher number density. If the upper volcanic plume were a mix of
213   optically thin and thick layers, the height retrieval count profile would indicate an approximate
214   upper-plume thickness of 4-5 km. However, as noted, optically thick parts will obscure material
215   below. From 07:06Z to 10:06Z, the upper volcanic plume obscures the lower cold umbrella,
216   decreasing its retrieval numbers, but as the upper volcanic plume moves out of the mesoscale
217   domain, retrievals increase for the slower evolving cold umbrella. Subsequent activity is seen in
218   the volcanic plume retrieval peaks between 07:00Z and 09:00Z that do not surpass height of the
219   initial eruption, for which earlier plume material has advected out of the mesoscale domain. This
220   interpretation is supported by the animation of the stereo retrievals provided in the supplemental
221   material. Overall, the plume ceiling within the mesoscale domain is observed to fall nearly
222   linearly at a rate of ~1.7 km/h.

223

224   **Figure 3.** A time series of the distribution of plume height retrievals shows the evolution over a
225   nearly 7-hour period. Advection out of the mesoscale domain and thinning of the higher-level
226   plume causes more of the cold umbrella near the tropopause to be revealed as time progresses.
227   4.3 Radio Occultation Results

228   The GNSS-RO technique has been used operationally in numerical weather prediction to
229   provide temperature information in the lower stratosphere and upper troposphere through the
230   bending induced by atmospheric refractivity (Healy et al., 2005). Bending Angle (BA) is the
231   critical parameter used to profile atmospheric variability from GNSS-RO and increases
232   exponentially as the surface approaches. This study uses near real-time data from the

233   Constellation Observing System for Meteorology, Ionosphere and Climate-2 (COSMIC-2), and
234   Spire under NOAA's Commercial Weather Data Pilot (CWDP) program.

235   To detect volcano-induced BA perturbations on January 15, we first derive a BA
236   reference profile for the latitude band (15°S to 25°S) using all BA profiles from January 14 and
237   16. Then, we take the difference between individual profiles from January 15 and the reference
238   BA to find anomalies near the Tonga eruption region. The BA perturbation is measured in
239   percentage from the difference divided by the reference BA. Typically, a BA profile varies
240   within 10% about the reference at heights between 20-40 km.

241   As shown in Figure 4, two strong BA perturbations are observed around 05:17:40Z (from
242   COSMIC-2) and 05:12:42Z (from Spire), indicating an ~50% deviation from the reference. The
243   top heights of the BA perturbations are approximately 41 km and 38 km, respectively for these
244   cases. The GNSS-RO technique has a relatively good (< 2 km) vertical but poor (~300 km)
245   horizontal resolution. Thus, the bending is sensitive to the refractivity change induced by a large
246   volcanic plume like that of the Tonga eruption. The top of the BA perturbation indicates the first
247   height where the RO line-of-sight encounters the volcanic plume. Starting with the average of
248   the two RO measurements, 39.5 km at 05:15Z, and extrapolating forward with the fall rate of 1.7
249   km/h (identified in Figure 3) until 07:06Z predicts a maximum plume top of 36.4 km. This
250   agrees with the highest retrievals in the 07:06Z histogram to the expected vertical resolution of
251   the RO observations.

252

Figure 4. Perturbations of the Bending Angle (BA) profile observed by COSMIC-2 and Spire
GNSS-RO from 15 January 2022 with respect to the reference profile. The sharp BA change in
the stratosphere indicates the impact of the volcanic plume on radio-wave propagation. The plot
indicates the locations and times of the RO profiles.

4 Conclusions

258   We used GOES-17 and Himawari-8 geostationary satellite imagery to study the 15 January 2022
259   eruption of the Hunga Tonga-Hunga Ha'apai volcano shortly after 04:00Z. Manually measured
260   parallaxes between near-simultaneous visible images from each satellite and the lengths of
261   shadows cast by the plume provided information about plume structure in the earliest phases of

262 the eruption. We applied a stereo-winds tracking method starting at 07:06Z to automatically
263 generate a high-density representation of plume advection jointly retrieved with plume height.
264 This powerful method provided a detailed mesoscale description of advection and vertical
265 structure for nearly seven hours every 10 minutes.

266 Our results show that the Hunga Tonga-Hunga Ha'apai volcano ejected material as high as 55
267 km, with a substantial amount of material injected above 30 km. Such peak altitudes exceed the
268 maximum column altitudes of 40 km reported for the 1991 Mount Pinatubo eruption by Holasek
269 et al. (1996). As the eruption progressed and later died down, advection carried much of the
270 injected stratospheric plume outside the mesoscale domain studied. The plume remaining in the
271 mesoscale domain would have thinned or collapsed to render it untrackable in the IR imagery.
272 Our analysis of GNSS-RO bending angles confirms that material was lofted between 30 km and
273 40 km approximately one hour after the initial eruption.
