8 **Key Points:**

9 • A flood inundation model is developed, based on low-fidelity hydrodynamic
10 modelling, spatial analysis, and Gaussian Process learning (LSG).

11 • The LSG model predicts water depths with a mean RMSE of 4 cm and a standard
12 deviation of 5 cm.

13 • The LSG model is 12 times faster than a traditional high-resolution hydrodynamic
14 model.

15

16 **Abstract**

17 High computational cost is often the most limiting factor when running high-resolution

18 hydrodynamic models to simulate spatial-temporal flood inundation behaviour. To address

19 this issue, a recent study introduced the hybrid Low-fidelity, Spatial analysis, and Gaussian

20 Process learning (LSG) model. The LSG model simulates the dynamic behaviour of flood

21 inundation extent by upskilling simulations from a low-resolution hydrodynamic model

22 through Empirical Orthogonal Function (EOF) analysis and Sparse Gaussian Process (Sparse

23 GP) learning. However, information on flood extent alone is often not sufficient to provide

24 accurate flood risk assessments. In addition, the LSG model has only been tested on

25 hydrodynamic models with structured grids, while modern hydrodynamic models tend to use

26 unstructured grids. This study therefore further develops the LSG model to simulate water

27 depth as well as flood extent and demonstrates its efficacy as a surrogate for a high-resolution

28 hydrodynamic model with an unstructured grid. The further developed LSG model is

29 evaluated on the flat and complex Chowilla floodplain of the Murray River in Australia and

30 accurately predicts both depth and extent of the flood inundation, while being 12 times more

31 computationally efficient than a high-resolution hydrodynamic model. In addition, it has been

32 found that weighting before the EOF analysis can compensate for the varying grid cell sizes

33 in an unstructured grid and the inundation extent should be predicted from an extent-based

34 LSG model rather than deriving it from water depth predictions.

35 **Plain Language Summary**

36 Every year, lives are lost, and infrastructure is destroyed due to floods. This highlights the

37 need for fast and accurate flood predictions to inform flood forecasting and risk assessments.

38 However, predicting flood inundation in high resolution is often not practically feasible due

39 to the high computational cost involved in running complex computer models. Simplified

40 computer models can be used to provide faster flood predictions, but they lack the accuracy

41 provided by complex models. To address this issue, this study evaluates an alternative

42 method based on the combination of a fast simple model together with an advanced spatial

43 feature matching method. The advanced spatial feature matching method is used to convert

44 the predictions obtained from the simple model to accurate predictions of flood inundation

45 depth and extent. The new approach is applied to a large floodplain in Australia and different

46 adaptations are explored to optimise the procedure and ensure robust performance. The new

47 approach is compared to the use of a traditional complex model and a previous approach that

48    only predicted inundation extent. The new approach shows similar accuracy to the traditional

49    complex model while being  12 times faster, thereby making it more practically useful for

50    flood risk assessments.

## 1 Introduction

52        Each year, flooding causes massive destruction of infrastructure and loss of lives all

53    around the world. Taking Australia as an example, the cost of the 2011 Queensland floods

54    was AU$2.38 billion (Australian Institute for Disaster Resilience, 2012), and the 2022

55    February-March floods in Queensland and New South Wales caused damages of AU$4.8

56    billion (The Insurance Council of Australia, 2022). Another example is the 2022 floods in

57    Pakistan that have killed around 1,500 people and displaced more than 33 million people

58    (Goldbaum & ur-Rehman, 2022). With future climate prediction, the recurrence of such

59    flooding events is only expected to increase (IPCC, 2021; Kirezci et al., 2020), highlighting

60    the need for effective modelling techniques to assist risk assessment, design of new

61    infrastructure and real-time forecasting.

62        Flood inundation is traditionally modelled using high-resolution two-dimensional

63    (2D) hydrodynamic models that simulate the physical processes of the flood event from a set

64    of boundary conditions (Bates, 2022; Razavi et al., 2012; Teng et al., 2017). These models

65    can simulate flood inundation accurately with a high degree of realism and hence are often

66    referred to as high-fidelity models (Razavi et al., 2012). However, due to the degree of detail

67    needed (high resolution) and the complex nature of flood events, the computational costs of

68    high-fidelity models are often too high for these models to be used for real-time modelling

69    and flood risk assessment through ensemble modelling, where hundreds or thousands of

70    model realisations are needed (Teng et al., 2017; Wu et al., 2020). To improve the

71    computational efficiency of high-fidelity models, researchers have explored parallel and

72    high-performance computing (Neal et al., 2009; Sanders & Schubert, 2019), graphics

73    processing unit (GPU) technologies (Ming et al., 2020; Morales-Hernández et al., 2021), and

74    more efficient solution algorithms (Bates & De Roo, 2000; Sridharan et al., 2021). Although

75    these methods have been shown to improve the computational efficiency of the simulations,

76    the use of high-fidelity hydrodynamic models to simulate flood inundation of large regional-

77    sized domains (>100 km$^2$; Bentivoglio et al. (2022)) with high resolution (1-100 m) continues

78    to present computational challenges for practical applications involving real-time ensemble

79    forecasts. To address this issue, researchers have developed surrogate models to provide

80　approximate flood inundation simulations with a lower computational burden than high-

81　fidelity models (Razavi et al., 2012).

82　　　　Various types of surrogate models have been developed, and they can be divided into

83　three categories based on the model structure: Conceptual, Low-fidelity and Emulator

84　models. Conceptual models are based on simple hydraulic concepts and are normally very

85　fast, but they cannot capture dynamic behaviour (e.g. Lhomme et al. (2008); Nobre et al.

86　(2016); Teng et al. (2019)). Low-fidelity models are physics-based hydrodynamic models

87　which are faster but of lower accuracy compared to high-fidelity models (e.g. Altenau et al.

88　(2017); Bates and De Roo (2000); Bomers et al. (2019); Liu et al. (2019)). Emulator models

89　are data-driven models, which are very fast and are able to predict complex relationships

90　accurately; however, they cannot capture spatial correlation and are often restricted to low-

91　dimensional data (e.g. Chu et al. (2020); Kabir et al. (2021); Xie et al. (2021); Zhou et al.

92　(2021)). Additional information on each surrogate type can be found in the literature reviews

93　by Asher et al. (2015); Bates (2022); McGrath et al. (2018); Razavi et al. (2012); Teng et al.

94　(2017).

95　　　　All three types of surrogate models have advantages and limitations. This has led to

96　the concept of developing hybrid approaches that combine the benefits of multiple models

97　whilst overcoming some of the limitations. One of the most recent hybrid models is the Low-

98　fidelity, Spatial analysis, and Gaussian Process learning (LSG) model developed by Fraehr et

99　al. (2022). The LSG model accurately simulates the dynamic behaviour (e.g. the rising and

100　recession components, and hysteresis) of flood inundation at a lower computational cost than

101　high-fidelity models. The LSG model first uses a low-fidelity model to simulate flood

102　inundation on a coarsely discretised grid. Due to the coarse resolution of the low-fidelity

103　model, the simulation time is significantly faster than using a high-fidelity model, but the

104　accuracy is also reduced. Thus, the primary purpose of the low-fidelity model in the LSG

105　methodology is to capture the temporal and spatial dependencies of flood behaviour in a

106　computationally efficient way. While the low-fidelity simulation step is fast, the accuracy of

107　the simulations needs to be improved to make the predictions useful for practical purposes.

108　This can be done by developing a relationship between low- and high-fidelity model

109　predictions based on a training dataset, and then using this relationship to upskill the accuracy

110　of the low-fidelity simulations (e.g. Yang et al. (2022) and Carreau and Guinot (2021)). In the

111　LSG model, the upskilling of low-fidelity predictions is carried out by first applying

112　Empirical Orthogonal Function (EOF) analysis to reduce the dimensionality of the low-

113    fidelity data into a small number of independent features. The dimension reduction of the

114    EOF analysis facilitates the training of a Sparse Gaussian Process (GP) model to convert the

115    key low-fidelity features to high-fidelity features. GP models have been used in numerous

116    studies and perform well in describing non-linear relationships (e.g. Contreras et al. (2020);

117    Ma et al. (2019); Parker et al. (2019)), but they are computationally demanding to optimise

118    for large datasets (Bauer et al., 2016; Burt et al., 2019). For this reason, a Sparse GP model is

119    used in the LSG methodology as it provides a high level of computational efficiency by

120    approximating the full GP model by a set of assumptions (Leibfried et al., 2021). After the

121    conversion through the Sparse GP model, the predicted high-fidelity features can be used to

122    reconstruct flood inundation surfaces with high resolution and accuracy without needing to

123    run a high-fidelity model.

124    Although Fraehr et al. (2022) demonstrated the good performance of the LSG model,

125    the methodology was only applied to the simulation of inundation extent and timing of a

126    flood event and not the water depth. Information on water depth is important to correctly

127    represent the degree of hazard associated with a predicted inundation extent of a flood event

128    (Hunter et al., 2007), and is a key indicator in warning systems and for estimating flood

129    losses (Antony et al., 2021; Chang et al., 2019; Zischg et al., 2018). For those reasons, further

130    development of the LSG model to predict the temporal-spatial distribution of water depths in

131    inundated areas would make the LSG model substantially more useful for risk assessment.

132    However, continuous variables, like water depth, are generally harder to predict accurately

133    than binary (i.e. wet/dry) indicators of inundation. This means that deriving inundation extent

134    from water depth predictions instead of directly predicting inundation extent might affect the

135    accuracy of the LSG model. Accordingly, there is value in extending the development of the

136    LSG model to accommodate water depth predictions to determine whether there is any

137    reduction in the accuracy of the simulations.

138    Furthermore, in the study by Fraehr et al. (2022) the LSG model was only applied to a

139    coupled 1D-2D hydrodynamic model that had a structured quadratic grid (i.e. one which

140    provided predictions at regular spacing throughout the model domain without increasing grid

141    resolution in areas of interest). A coupled 1D-2D model uses a 1D component to simulate the

142    flow and water depth in the mainstream of the river, and a 2D component to simulate

143    inundation of the floodplain. Although this type of hydrodynamic model has been shown to

144    provide good performance historically, modern hydrodynamic inundation models tend to be

145    fully 2D and utilise unstructured (i.e. irregular or flexible) grids to describe complex

146    geometries (Bates, 2022; Teng et al., 2017). Enabling the LSG model to accommodate

147    unstructured grids will thus expand the possible applications of the model and strengthen its

148    relevance to current practice.

149         In unstructured grids, cell sizes vary across the model domain, and it is a common

150    practice to take these differences into account to ensure good model performance. Varying

151    cell sizes are commonly seen in climate science and oceanography, where latitude-longitude

152    grids with converging meridians are used. EOF analysis is also used in these research areas,

153    where it is normal to compensate for irregular grids by applying weights according to the size

154    of the grid cells before the EOF analysis (Baldwin et al., 2009; Hannachi et al., 2007). The

155    general idea behind area-weighting is to ensure that larger cells are not valued equally to

156    smaller cells. However, the general principle of area-weighting might not be applicable in

157    flood inundation modelling as larger cells are normally located on the floodplain and smaller

158    cells in the river regions, noting that flow behaviour on floodplains is generally more

159    gradually varying than flow within the main channel. Adopting a weighting scheme in the

160    LSG model that is directly proportional to grid cell area could be problematic as this would

161    give small cells located in regions of rapidly varying flow low weight, which may potentially

162    reduce the accuracy of the model. Therefore, the effect that weighting has on the performance

163    of the LSG model needs to be investigated to determine how the LSG model can be

164    successfully applied to unstructured grids.

165         In this study, we further develop the methodology of the LSG model to simulate water

166    depth and thereby strengthen the model's capabilities for the challenges encountered in

167    practical applications. To investigate how the new developments affect the accuracy, the

168    predictions of flooding extent obtained from the revised LSG model are compared to both a

169    high-fidelity model as well as the original LSG model. The versatility of the LSG model is

170    explored by applying the LSG model to a 2D hydrodynamic model with an unstructured grid

171    to simulate flood inundation on the flat and complex Chowilla floodplain in Australia. In this

172    application, we use a low-fidelity model that is considerably coarser than the model used

173    previously in the study by Fraehr et al. (2022) to test the upskilling and speed-up capabilities

174    of the LSG methodology even further. Through this application, it is also investigated how

175    weighting before the EOF analysis affects the accuracy of the LSG model and whether this

176    should be used when applying the LSG model on an unstructured grid.

**2 Methodology of the LSG model**

The overall concept of the LSG model is to rapidly derive accurate inundation estimates using information previously obtained from a small number of low- and high-fidelity model simulations, a process that avoids the computational burden of running a detailed hydrodynamic model for every set of new boundary conditions. This significantly enhances the computational efficiency without great loss of accuracy and represents a practical means of providing rapid estimates of complex flood behaviour. The LSG model predicts inundation by upskilling inundation predictions from a low-fidelity model simulation. The upskilling is done by using EOF analysis to reduce the dimensionality of the spatial-temporal inundation behaviour through EOF analysis. Essentially, EOF analysis is a means to identify a modest number of independent components that are representative of the spatial and temporal patterns of inundation behaviour. This is necessary as data-driven emulator models are not well suited to capturing spatial correlation and perform best when applied to low-dimensional data. After the EOF analysis, a Sparse GP model is used to convert the low-fidelity temporal components to high-fidelity temporal components. Finally, the high-resolution inundation prediction is obtained by reconstructing the hydrodynamic results through reverse EOF analysis using the predicted high-fidelity temporal components together with the high-fidelity spatial components.

In the following, we describe the details of the methodology of the LSG model for predicting water depth, and at the end of this section, we explain how the methodology differs from the one previously proposed by Fraehr et al. (2022).

2.1 Training of LSG model

Before the LSG model can be used to predict flood inundation, it needs to be set up and trained. There are 6 steps involved in the LSG model training as shown in Figure 1. Steps 1, 2 and 3 and Steps 1, 4 and 5 involve deriving key spatial-temporal components through EOF analysis for the high- and low-fidelity data, respectively. The key temporal components are thus used in Step 6 to train the Sparse GP model. The details of the individual steps are explained in the following sections.
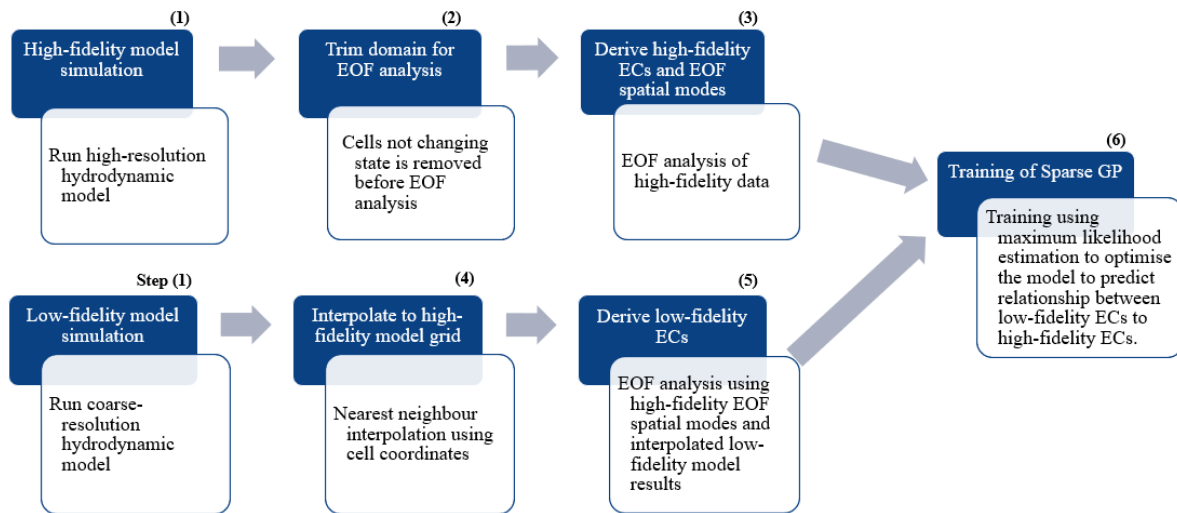

**Figure 1: Workflow of training of the LSG model.**

2.1.1 Step 1: Creation of training dataset

A training dataset is needed to facilitate the EOF analysis and training of the Sparse GP model. To create a training dataset for the LSG model, high- and low-fidelity models have to be set up for the specific study area. First, the high-fidelity model is set up and calibrated. Second, the low-fidelity model is created, normally by simplifying the high-fidelity model. Thus, the training dataset is created by first running the high-fidelity model for a large number of flood events, and then running the low-fidelity model for the same flood events. The training events must span a wide range of inundation behaviour to ensure the model performance is sustained for new events not included in the training.

2.1.2 Step 2: Trim model domain for EOF analysis

When simulating flood inundation over a computational grid, some cells never get flooded. These cells do not contain any valuable information and therefore only slow down the EOF analysis in Step 3. Thus, by trimming the spatial domain to only contain cells that change state (changes in water depth) during the training events, the EOF analysis can be performed more efficiently (noting that the training events must cover the full range of conditions expected in the future to ensure all potential flood-prone areas are included after the trimming.). The trimming is carried out by categorising the cells into two groups, namely: "dry" and "wet" cells. The wet cells are those whose water depth varies throughout the training events and are therefore the only ones included in the EOF analysis. A threshold of 3 cm water depth is applied to differentiate dry and wet cells and reduce noise.

227    2.1.3 Step 3: Reducing dimensionality of high-fidelity data through EOF analysis

228         The high dimensionality of the spatial-temporal high-fidelity dataset cannot easily be

229    captured using a Sparse GP model. To address this issue, EOF analysis is used to reduce the

230    dimensionality of the dataset while maintaining the spatial and temporal correlation. EOF

231    analysis deconstructs spatial-temporal datasets into pairs of spatial and temporal components.

232    Each pair of spatial and temporal components is referred to as a mode, where the spatial

233    components are called spatial maps (EOFs) and the temporal components are called

234    expansion coefficients (ECs). All modes are orthogonal to the others (i.e. they are fully

235    independent of one another), and the EOF analysis aims to find a linear combination of

236    modes that maximizes the variance of the dataset (Jolliffe & Cadima, 2016).

237         To find the modes, we first assemble a $T \times N$ matrix called $D_{HF}$ containing the

238    simulated water depths from the high-fidelity model. $T$ is the number of timesteps in the

239    training dataset and $N$ is the number of wet cells found through categorisation in Step 2. Each

240    column in $D_{HF}$ is detrended by subtracting the temporal mean. This ensures centring of the

241    data to a mean of zero.

242    2.1.3.1 Applying weighting in the EOF analysis

243         The next step in the EOF analysis is to decide whether to perform weighting or not.

244    Weighting is included by multiplying $D_{HF}$ with a vector containing the weights for each cell

245    included in the EOF analysis.

246         As described in the introduction, weighting according to cell sizes is normally used to

247    compensate for varying grid cells in unstructured grids in the areas of climate science and

248    oceanography (Baldwin et al., 2009; Hannachi et al., 2007). The purpose of the weighting is

249    to ensure larger cells, which account for a larger proportion of the model domain, are

250    weighted higher. However, in hydrodynamic modelling of flood inundation, the smaller grid

251    cells are usually located in the regions of rapidly varying flow (e.g. rivers), and it is important

252    to simulate flow behaviour in these areas precisely. Weighting according to cell sizes could

253    therefore affect the accuracy of the LSG model as the river regions would be given a low

254    weight. On the other hand, not including weighting might not represent flood behaviour in the

255    larger cells on the floodplain correctly, which could thus affect the accuracy of the inundation

256    predictions. To examine the importance of weighting, this study builds two versions of the

257    LSG model, one weighted and one unweighted, and applies them to simulate inundation on

258    an unstructured grid (See section 3).

259    2.1.3.2 Performing EOF analysis and deriving significant modes

260        Finally, after deciding to apply weighting or not, the modes are found via singular

261    value decomposition of $D_{HF}$, following equation (1).

$$D_{HF} = U_{HF} \cdot C_{HF} \approx \sum_{k=1}^{K} U_{HF}(k,:) \cdot C_{HF}(:,k) \tag{1}$$

262    where $U_{HF}$ is a $T \times N$ matrix where each row is an EOF spatial map, $C_{HF}$ is a $T \times T$ matrix

263    where each column corresponds to an EC temporal function.

264        After retrieving the modes, they are ranked according to the proportion of the

265    dataset's variance they explain. The dimension reduction of the EOF analysis thereby lies in

266    selecting only a few ($K$) significant modes that describe the majority of the variance in the

267    dataset. These modes are chosen by satisfying both North's test, where a mode is considered

268    significant if its eigenvalue lies outside the error limits of the eigenvalue for the previous

269    mode (North et al., 1982), and Kaiser's Rule, where the eigenvalue should be above 1

270    (Kaiser, 1960). Once the $K$ significant modes are found, they can be used to reconstruct $D_{HF}$

271    with little loss of information. To assist the understanding of the EOF analysis, an example is

272    given in the supporting information.

273    2.1.4 Step 4: Interpolate low-fidelity data to high-fidelity grid

274        The low-fidelity ECs can be derived using the high-fidelity spatial modes (See Step

275    5). This ensures the same basis of EOF spatial modes is used for both the high- and low-

276    fidelity ECs and is a more computationally efficient process compared to performing EOF

277    analysis from scratch due to the time-consuming derivation of the covariance matrix and

278    eigenvalue decomposition. To facilitate the low-fidelity ECs derivation, the low-fidelity

279    water surface elevations (water depth + terrain elevation) are interpolated to the high-fidelity

280    grid using a nearest-neighbour method. After the interpolation, the areas where the terrain

281    elevation of the high-fidelity cell is higher than the interpolated low-fidelity water surface

282    elevation are assumed dry. This reduces the extent of the interpolated low-fidelity results, and

283    initial tests have shown that it helps minimise overestimation of the inundation extent for the

284    LSG model.

285    2.1.5 Step 5: Derive low-fidelity ECs

286        The low-fidelity ECs are derived by inserting the interpolated low-fidelity data into a

287    $T \times N$ matrix called $D_{LF}$. Since the low-fidelity data has been converted to the high-fidelity

288  grid in Step 4, the $D_{LF}$ and $D_{HF}$ matrices have the same dimensions. Detrending is performed

289  by subtracting the high-fidelity temporal mean derived for $D_{HF}$ in Step 3. The high-fidelity

290  temporal mean is used to detrend the low-fidelity data to ensure comparability between $D_{LF}$

291  and $D_{HF}$, and as this mean is used in Step 9 for reconstruction of the high-resolution flood

292  inundation. Finally, after detrending, the optional weighting is applied and the high-fidelity

293  EOF spatial maps $U_{HF}$ are used to derive the low-fidelity ECs in equation (2).

$$C_{LF} = D_{LF} \cdot U'_{HF} \tag{2}$$

294  where $C_{LF}$ is a $T \times T$ matrix containing the low-fidelity ECs, and $U'_{HF}$ is the transpose of $U_{HF}$.

295  This approach is applied in a similar way by Zhao et al. (2022) to calibrate precipitation

296  fields.

297  2.1.6 Step 6: Training of the Sparse GP model

298  Once both the low- and high-fidelity ECs have been derived for the training dataset,

299  they can be used to train a Sparse GP model to predict the high-fidelity ECs from the low-

300  fidelity ECs.

301  GP models assume the relationship between input and output follows a Gaussian

302  distribution of functions, and by doing so, can predict non-linear relationships with statistical

303  confidence (see Equation (3)) (Rasmussen & Williams, 2006).

$$GP(x) \sim \mathcal{N}(m(x), k(x, x')) \tag{3}$$

$$k(x, x') = \sigma_f^2 \exp\left(-\frac{x - x'}{2l}\right) + \sigma_n^2 \tag{4}$$

304  where $GP(x)$ is the Gaussian function, $m(x)$ is the mean function, $k(x, x')$ is the covariance

305  function (kernel) and $x$ is the input variable, in this case, the low-fidelity ECs in $C_{LF}$. In the

306  kernel function, $\sigma_f^2$ is the signal variance, $l$ is the lengthscale, $\sigma_n^2$ is the noise variance and

307  $x - x'$ is the Euclidean distance between inputs. As the data has been detrended in Steps 3

308  and 5, the mean function can be assumed to be zero (Rasmussen & Williams, 2006). For the

309  kernel, an Exponential kernel function is used to describe the covariance (see Equation (4)),

310  following Fraehr et al. (2022).

311  The reason for using a Sparse GP in the LSG model instead of the standard full GP

312  model is due to the high computational demand of the full GP model. A GP model is

313  optimised using maximum likelihood estimation, which requires an inversion of the

314    covariance matrix. This inversion has a computational demand of $\mathcal{O}(T^3)$ and makes the full

315    GP model infeasible to be used for large datasets (Bauer et al., 2016; Leibfried et al., 2021).

316    To address this issue, the Sparse GP model uses a number $M$ of inducing variables, which

317    should be significantly less than the $T$ number of timesteps in the training dataset. The

318    inducing points are a reduced set of input variables that are optimised to approximate the full

319    GP model, and thereby reduces the cost of the matrix inversion to $\mathcal{O}(TM^2)$ (Snelson &

320    Ghahramani, 2006; Titsias, 2009). The Sparse GP model chosen for the LSG model is based

321    on variational inference, as this has been shown to improve with an increasing number of

322    inducing variables (Bauer et al., 2016).

323        In the LSG model, individual Sparse GP models are used to predict each significant

324    mode of the high-fidelity ECs, resulting in a total of $K$ models (See Figure 2). Each Sparse

325    GP model receives all low-fidelity ECs as input and predicts one high-fidelity EC as output.

326    All inputs and outputs are standardised to zero mean and unit variance before incorporating

327    them into the Sparse GP models.

328        Each Sparse GP model is optimised using maximum likelihood estimation of the

329    hyperparameters: $\sigma_f^2$, $l$ and the inducing variables. The number of inducing variables is found

330    by a trial-and-error approach. For the application in this paper, 2% of the number of input

331    samples has shown to be a sufficient number of inducing variables, but for smaller datasets, a

332    larger proportion is most likely necessary. The optimisation process for the hyperparameters

333    is performed using the L-BFGS-B optimisation algorithm. More details of the initialisation

334    and optimisation of the hyperparameters can be found in Fraehr et al. (2022).

335

336   **Figure 2: ECs conversion using Sparse GP models.**

337   2.2 Prediction using the LSG model

338          After finalising the training phase, the LSG model can be used to predict flood

339   inundation by following the workflow in Figure 3. In the prediction workflow, Steps 1, 4 and

340   5 from the training workflow are grouped together in Step 7 and involve deriving the low-

341   fidelity temporal components through EOF analysis. In Step 8 the Sparse GP model is used to

342   convert the low-fidelity components to high-fidelity components and finally, in Step 9 the

343   flood inundation is reconstructed in high-resolution.

344

345   **Figure 3: Workflow of prediction using the LSG model.**

346   2.2.1 Step 7: Run the low-fidelity model and derive the low-fidelity ECs

347          In the prediction phase, only the fast low-fidelity model needs to be run to simulate

348   the flood inundation. This is what makes the LSG model more computationally efficient than

349   using a high-fidelity model. The low-fidelity is run for a new unseen event and the simulation

350   results are converted to low-fidelity ECs, following the process described in Steps 4 and 5

351   (Note: It is still the high-fidelity EOF spatial maps from the training data that are used to

352   derive the low-fidelity ECs. This ensures the ECs are comparable between events.).

353    2.2.2 Step 8: Predict high-fidelity ECs using the Sparse GP model

354         The low-fidelity ECs are used as input to the Sparse GP models to predict the high-

355    fidelity ECs, which can then be used to reconstruct the flood inundation. The Sparse GP

356    model provides both a mean and variance of the predictions (Rasmussen & Williams, 2006).

357    2.2.3 Step 9: Inverse EOF analysis to reconstruct flood inundation

358         By assembling the predictions of high-fidelity ECs into a matrix $\widehat{C_{LSG}}$, a high-fidelity

359    prediction of flood inundation is obtained by reversing the EOF analysis to reconstruct the

360    temporal-spatial inundation data from temporal functions of ECs and EOF spatial maps using

361    Equation (5).

$$\widehat{D_{LSG}} = \sum_{k=1}^{K} U_{HF}(k,:) \cdot \widehat{C_{LSG}}(:,k) \tag{5}$$

362    where $\widehat{D_{HF}}$, after re-adding the high-fidelity temporal mean subtracted before the EOF

363    analysis in Step 3, is the LSG model's temporal-spatial prediction of flood inundation.

364         When reconstructing the inundation, the first $K$ significant modes do not explain all

365    the variance in the dataset. This means that there are minor deviations (noise) in the water

366    depth prediction causing otherwise dry areas to appear to be inundated by insignificant

367    shallow water depths. To address this issue, a threshold of 3 cm water depth is applied. This

368    alleviates the problem of the LSG model predicting insignificant flooding in some cells.

369    Finally, the dry cells identified in Step 2 are added to the $\widehat{D_{LSG}}$ matrix to reconstruct the full

370    prediction of flood inundation.

371    2.3 The LSG model for directly predicting flood extent

372         Although the extent of flood inundation is usually derived from water depth

373    predictions, it can also be predicted directly, as is the case in the previously proposed LSG

374    model in Fraehr et al. (2022). Predicting the flood extent directly might result in higher

375    accuracy for the flood extent, as this bypasses the process of deriving the flood extent from

376    water depth predictions and the potential error from this derivation. To examine how the

377    accuracy of predicting the flood extent directly compares to deriving it from water depth

378    predictions, we construct both types of LSG models (See section 3 for further details on the

379    comparison).

380     In the following, we show the differences in the LSG model for direct extent

381     prediction purposed by <u>Fraehr et al. (2022)</u> compared to the approach presented here to

382     predict water depth. Only the steps that differ from the workflow in sections 2.1 and 2.2 are

383     presented.

384     2.3.1 Step 2: Convert to binary values before trimming the model domain

385     The high-fidelity model results in the training dataset are converted to binary values

386     (1 for flooded, 0 for dry) by applying a threshold of 3 cm water depth. This binarization

387     facilitates categorising the cells into three groups: dry, always wet, and temporary wet (TW).

388     Only the TW cells change state when using binary values and are therefore the only ones

389     included in the EOF analysis.

390     2.3.2 Step 3: Perform EOF analysis only on temporarily flooded cells

391     With the new categories of cells, the EOF analysis is performed only on TW cells.

392     This results in a $D_{HF}$ matrix that is $T \times N_{TW}$. $N_{TW}$ is the number of TW cells identified. The

393     EOF analysis is still performed using Equation (1).

394     2.3.3 Step 4: Interpolation of low-fidelity binary data

395     In <u>Fraehr et al. (2022)</u> the interpolation of the low-fidelity data to the high-fidelity

396     grid is performed using binary values. Binary values cannot easily be related to terrain

397     elevation, and for that reason, there was no filtering of areas where the water surface

398     elevation of the low-fidelity model was below the terrain elevation of the high-fidelity cell.

399     However, in the LSG model for direct extent prediction used in this study, we include

400     filtering based on the water surface elevation as in Step 4 for the LSG model for water depth

401     predictions (See section 2.1.4). This is an improvement over the previous methodology and

402     ensures the same high-fidelity model cells are used in both the water-depth and extent-based

403     versions of the LSG model.

404     2.3.4 Step 9: Binary threshold to reconstruct data

405     As mentioned in section 2.2.3, not all of the variance in the dataset is explained via

406     the $K$ significant modes. When reconstructing the flood extent, this results in noise, so the

407     values do not completely reconstruct to 1 (flooded) or 0 (dry). To address this issue and

408     convert the predictions to fully binary values, a threshold of 0.5 is used. The full prediction of

409     the flood extent is thus reconstructed by adding the always wet and dry cells identified in

410     Step 2 to the $\widehat{D_{HF}}$ matrix.

**3 Evaluation of LSG model for water depth predictions**

In this study, a new LSG model for water depth predictions is proposed. However, as discussed in Step 3 of the methodology (See section 2.1.3.1), it needs to be examined how weighting according to grid cell sizes affects the accuracy of the LSG model when applied to an unstructured grid. Applying weights will give the larger cells normally located on the floodplain a higher weight than the smaller cells in the river regions. The rivers are normally the source of flooding and giving a smaller weight to these areas could therefore potentially reduce the accuracy of the LSG model. We examine this by creating two versions of the LSG model, one with weighting that we call LSG-WD (Weighted) and one without weighting that we call LSG-WD (Unweighted). Both of the models are evaluated in their ability to provide comparable inundation simulations to a high-fidelity model.

Besides the two LSG models for water depth predictions, we also create a LSG model for direct flood extent predictions following the methodology in Fraehr et al. (2022). To ensure that the same high-fidelity cells are used in all the LSG models tested in this study, we made one slight change to the methodology and adopted the same interpolation strategy as used to predict water depths where water surface elevation below the terrain elevation is assumed dry (See 2.3.3 for further details). We name this model LSG-EXT (Weighted) and use this to examine if the accuracy of the flood extent predictions is influenced by the use of water depth predictions compared to predicting the extent directly, as in the previous version of the LSG model (noting that only a weighted version is used for direct extent prediction as this was advocated by Fraehr et al. (2022) for unstructured grids, although it was not tested). If the accuracy is significantly higher by directly predicting the extent, it might be worth considering using two LSG models, one for predicting flood extent directly and one for predicting water depth for those areas predicted as being flooded.

3.1 Evaluation of water depth predictions

The LSG models' ability to predict water depth is evaluated using Root Mean Square Error (RMSE) in Equation (6):

$$RMSE = \sqrt{\frac{1}{T}\sum_{t=1}^{T}\left(y^{LSG}(t) - y^{HF}(t)\right)^2} \tag{6}$$

where $y^{LSG}$ is the LSG prediction and $y^{HF}$ is the high-fidelity simulation.

439    Furthermore, the results are plotted as a scatter plot to examine if the LSG model

440    generally over- or under-predicts the water depth compared to the high-fidelity model. The

441    low-fidelity model simulation will be used as a benchmark for comparison.

442    3.2 Evaluation of inundation extent predictions

443    The overall prediction of inundation extent is evaluated using the same metrics as

444    used by Fraehr et al. (2022), that is Relative RMSE (relRMSE), Relative Peak Value Error

445    (relPeakValErr) and Relative Peak Time Error compared to the peak period (relPeakTimeErr)

446    in Equations (7), (8), and (9):

$$relRMSE = \frac{\sqrt{\frac{1}{T}\sum_{t=1}^{T}(A_{LSG}(t) - A_{HF}(t))^2}}{\frac{1}{T}\sum_{t=1}^{T}A_{HF}(t)} \tag{7}$$

$$relPeakValErr = \frac{\overline{A_{LSG}^{peak,5\%}} - \overline{A_{HF}^{peak,5\%}}}{A_{HF}^{peak,5\%}} \tag{8}$$

$$relPeakTimeErr = \frac{\overline{t_{LSG}^{peak,5\%}} - \overline{t_{HF}^{peak,5\%}}}{\max(t_{HF}^{peak,5\%}) - \min(t_{HF}^{peak,5\%})} \tag{9}$$

447    where $A_{LSG}$ is the inundation extent predicted using the LSG model, $A_{HF}$ is the inundation

448    extent from the high-fidelity simulation, $t_{LSG}^{peak,5\%}$ and $t_{HF}^{peak,5\%}$ are the timesteps of the peak

449    period, and "peak, 5%" indicates only the 5% peak values are used. A value close to 0

450    indicates a good prediction for relRMSE, relPeakValErr, and relPeakTimeErr.

451    The LSG model's ability to predict the spatial coverage of inundation is assessed

452    using Probability of Detection (POD), Rate of False alarm (RFA), and Critical Success Index

453    (CSI), following Equations (10), (11) and (12) (Schaefer, 1990):

$$POD = \frac{A_{detected}}{A_{detected} + A_{missed}} \tag{10}$$

$$RFA = \frac{A_{false\ alarm}}{A_{detected} + A_{false\ alarm}} \tag{11}$$

$$CSI = \frac{1}{\frac{1}{POD} + \frac{1}{1 - RFA} - 1} \tag{12}$$

454    where $A_{detected}$ are those areas correctly detected as being inundated or flooded, $A_{missed}$ are

455    areas simulated to be inundated using the high-fidelity model but are predicted to be dry

456 using the LSG model, and $A_{false\ alarm}$ are dry in the high-fidelity model simulation but

457 predicted as being inundated using the LSG model. The POD and RFA evaluate under- and

458 overestimation, respectively. The CSI is a comprehensive metric that combines the POD and

459 RFA metrics to provide an overall evaluation of the model's ability to predict the inundation

460 extent. A POD and CSI of 1 and RFA of 0 indicate a good model performance.

461 **4 Data and model application**

462 4.1 Study site

463 The study site chosen for the evaluation of the LSG models is the complex and flat

464 Chowilla floodplain (See Figure 4). The Chowilla floodplain is located in the lower part of

465 the Murray-Darling basin that has a total catchment area of approximately 1 million km²

466 (Murray-Darling Basin Authority, 2022). The area represented in the model domain is 740

467 km².

468 The Chowilla floodplain provides a challenging application for the LSG model, as it

469 contains the Murray River and includes several local minor streams, billabongs, and lakes; in

470 addition, flows in the Murray River are impacted by the operation of several weirs and

471 culverts (Murray-Darling Basin Authority, 2021), which help regulate water for irrigation

472 supply and environmental watering (South Australia - Department for Environment and

473 Water, 2022).

474 All of these features contribute to the complex inundation dynamics of the floodplain,

475 where flood inundation events can last several months due to the large upstream catchment

476 area and shallow gradient of the Murray River.

**Figure 4: Overview of the Chowilla floodplain study site and perimeter of the HEC-RAS model (ESRI, 2022).**

4.2 Hydrodynamic flood inundation models

4.2.1 High-fidelity model

The flood inundation in the Chowilla floodplain is simulated using a high-fidelity 2D hydrodynamic HEC-RAS model (Hydrologic Engineering Center's River Analysis System). HEC-RAS is a freely available flood modelling software developed by the US Army Corps of Engineers and simulates flood inundation using a diffusive wave model on an unstructured grid (US Army Corps of Engineers, 2021b). HEC-RAS uses a subgrid treatment to account for the hydraulic properties of the underlying terrain (Casulli, 2009; US Army Corps of Engineers, 2021a). Subgrid models are also known as porosity models and have been shown to perform well on coarse grids (Forest, 2020; Sanders & Schubert, 2019), which is advantageous in the development of the coarser low-fidelity model (See section 4.2.2). To the authors' knowledge, HEC-RAS is currently the only hydrodynamic modelling software that can apply subgrid treatment to an unstructured grid, thus making HEC-RAS particularly useful for exploring how the LSG model performs when simulating flood inundation using an unstructured grid, as described in section 3.

495        The high-fidelity HEC-RAS model has three inflow boundaries (Murray River,

496    Station no. 426200; Mullaroo Creek, Station no. 414211; and Lindsay River, Station no.

497    414212), and one water level outlet downstream at the Murray River Lock 5 upstream

498    (Station no. A4260512). All boundaries rely on historical data retrieved from a publicly-

499    available water data platform (Bureau of Meteorology, 2022). The locations of the boundaries

500    are shown in Figure 4.

501        The high-fidelity model simulates flooding using an unstructured grid with cell sizes

502    varying from 25 m along rivers and structures (weirs and control structures) up to 100 m on

503    the floodplain. The total number of grid cells in the model domain is 109,914 cells, and a

504    total of 796 river cross sections have been incorporated into the model bathymetry, which

505    also includes 22 weirs and control structures. The Manning n's roughness coefficient has

506    been calibrated to 0.026 s/m$^{1/3}$ in the river region and 0.083 s/m$^{1/3}$ on the floodplain. The

507    model was calibrated according to 6 water level stations located across the Chowilla

508    floodplain and Landsat 7 satellite images. The high-fidelity model is run at a fixed 20 s

509    timestep to ensure model stability. Further information on the setup and calibration of the

510    high-fidelity model is given in the supporting information.

511    4.2.2 Low-fidelity model

512        The low-fidelity model used in the LSG model is obtained by simply reducing the

513    resolution of the high-fidelity model. Fraehr et al. (2022) showed that using a low-fidelity

514    model with over 3 times larger cell sizes in the LSG model setup can provide comparable

515    results to the high-fidelity model. In this study, we test the capabilities of the LSG model

516    further by adopting an even coarser level of discretisation. In the low-fidelity model, a grid

517    cell size of 400 m is used along the rivers and on the floodplain, while the 25 m resolution

518    around weirs and structures is preserved. This reduces the number of grid cells to 4,916,

519    which is on average 1/20$^{th}$ of the high-fidelity model resolution.

520        Note that the only difference between the low- and high-fidelity model is the

521    computational grid. The boundaries and roughness coefficients are not changed. This is the

522    simplest way of developing the low-fidelity model, as no calibration is undertaken to account

523    for the change in spatial resolution. This approach is adopted as we want to examine if the

524    LSG model can upskill results despite having a poorly developed low-fidelity model. Due to

525    the larger grid cells, the low-fidelity model can be run at a steady timestep of 1 min without

526    showing signs of instability.

527 4.3 Flood events for training and validation

528       The high- and low-fidelity models are run for a number of flood events to create a

529 training dataset, as described in Step 1 of the LSG model (See section 2.1.1). For the

530 Chowilla floodplain, historic boundary data is available for the period 15/08/2010 to

531 18/06/2022. In this period, 10 historic flood events have been identified. The duration of the

532 events ranges from 75 to 306 days, with inundated areas ranging between 100 and 450 km².

533       In the inspection and initial simulations of the historic events, it was identified that

534 only 6 of the 10 historic events resulted in significant inundation of the floodplain. For

535 training the LSG model, a large training dataset spanning a wide range of inundation

536 behaviour is needed. It was therefore decided to create synthetic events by scaling and

537 extending the duration of the minor historic events. This procedure resulted in there being a

538 total of 29 events for training and validation (6 historic and 23 synthetic). Each event is

539 simulated using the high- and low-fidelity models, where flood information is saved every 6

540 hours. An overview of the duration and inundation extent for all the events is included in the

541 supporting information.

542       We use cross-validation to evaluate the performance of the LSG models. All 29 flood

543 events are divided into 10 groups based on the historic events from which they originate. In

544 the cross-validation, we train the LSG models on 9 groups and use the remaining group for

545 validation, resulting in a 10-fold cross-validation. This ensures events originating from the

546 same historic event are not used for validation when they are included in the training dataset.

547 **5 Results**

548       In this section, the water depth predictions using the developed LSG-WD (Weighted)

549 and LSG-WD (Unweighted) models are compared to examine the importance of using

550 weighting in the EOF analysis. Subsequently, the accuracy of the inundation extent of the

551 new water depth-based LSG model is compared to the LSG-EXT (Weighted) for direct extent

552 prediction, and finally, additional results of the difference in the EOF analysis and

553 computational efficiency for the LSG models are presented.

554 5.1 Water depth

555       The water depth predictions using the low-fidelity, LSG-WD (Weighted) and LSG-

556 WD (Unweighted) models are compared to the high-fidelity model using RMSE in Figure 5.

557 It is seen that the low-fidelity model on average has significantly higher RMSEs than the two

558  LSG models over all the 29 simulated events. This is expected as the low-fidelity model is

559  based on a considerably coarser grid resolution and is not calibrated. However, this also

560  shows the power of the LSG methodology to significantly reduce errors compared to the low-

561  fidelity model.

562  Comparing the LSG-WD (Weighted) and LSG-WD (Unweighted) model results does

563  not show any significant differences. For both models, the overall mean RMSE is 4 cm, and

564  the standard deviation is 5 cm. The highest errors are located close to the inflow boundaries

565  in the eastern areas and locally near the model boundaries in the western and north-western

566  parts of the Chowilla floodplain.
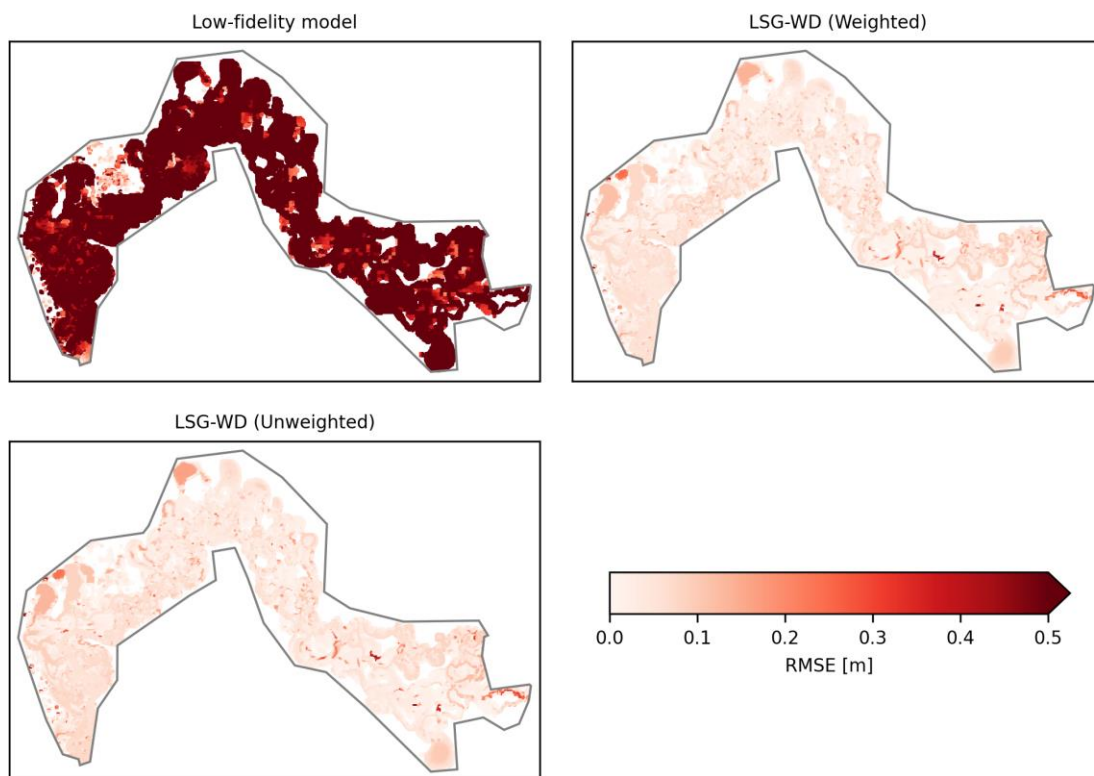

567

568

569  **Figure 5: Average RMSE for water depth predictions for all 29 simulated events using**

570  **the low-fidelity, LSG-WD (Weighted) and LSG-WD (Unweighted) models compared to**

571  **the high-fidelity model simulation.**

572  The improvement of using the LSG models compared to the low-fidelity model is also

573  evident from the boxplots showing the spread of RMSEs for each event in Figure 6.

574  Considering Figure 6b the LSG-WD (Weighted) show better accuracy for events 8a-8f and

575  10b, but the LSG-WD (Unweighted) show better accuracy for the remaining events, although

576  the difference between the two models is minimal. This shows that neither of the water depth-

577  based LSG models outperforms the other in predicting water depth and suggests that

578  weighting according to the grid sizes is of little importance when using the proposed LSG

579  methodology to predict water depth on an unstructured grid.

580

581

582  **Figure 6: Boxplots of RMSE between the low-fidelity, LSG-WD (Weighted) and LSG-**

583  **WD (Unweighted) models and the simulated water depth using the high-fidelity model.**

584  **a) shows the full range of RMSE, b) highlights the differences using weighting and no**

585  **weighting in the EOF analysis. Outliers are not shown. An overview of the events is**

586  **provided in the supporting information.**

587  The peak water depth is often of high concern in emergency response and flood risk

588  assessments, and a flood inundation model should therefore be able to predict this accurately.

589  The ability of the low-fidelity and LSG models to predict the peak water depth is evaluated

590  by comparing the simulated peak water depth from these models to those using the high-

591  fidelity model as shown in Figure 7. The figure shows the results of the peak water depth in

592  all 109,914 cells for all 29 simulated events (as a density map). A total of 3,187,506 data

593  points are compared for each model.

594  The low-fidelity model consistently overpredicts the water depth, both for shallow

595  and deeper depths, with a large spread in the predicted values. On the other hand, the LSG

596    models show good agreement with the high-fidelity model, illustrated by a coefficient of

597    determination approximately equal to 1. The prediction errors are heteroscedastic, generally

598    showing a narrower spread for large water depths and wider for shallower water depths. This

599    outcome is due to the flat topology of the Chowilla floodplain, which results in shallow

600    inundation depths that vary over a narrow range over most of the areas. There are no

601    distinctive differences between the LSG-WD (Weighted) and LSG-WD (Unweighted)

602    models, as both models show a good ability to predict the peak water depth.

603

604    **Figure 7: Peak water depth in each grid cell in the model domain predicted using the**

605    **low-fidelity, LSG-WD (Weighted) and LSG-WD (Unweighted) models compared to the**

606    **high-fidelity model simulation for all 29 simulated events. The density map shows light**

607    **and dark blue colours to indicate low and high data point density, respectively.**

608    5.2 Inundation extent

609        The inundation extents simulated using the high-fidelity model and the LSG models

610    are shown in Figure 8 for three representative events. Figures showing the inundation extent

611    for the remaining events are provided in the supporting information. The inundation extent is

612    found for the LSG-WD (Weighted) and LSG-WD (Unweighted) models by adopting a

613    threshold of 3 cm water depth to differentiate the cells into flooded and dry. This follows the

614    binary procedure adopted for mapping the flood extent in the LSG-EXT (Weighted) model

615    (See Step 2 in section 2.3.1). HEC-RAS has the ability to simulate partially flooded cells.

616    However, in this study, it was decided to simply use binary values to identify wet and dry

617    cells, to represent the results that would be obtained by other common hydrodynamic

618    modelling software, such as MIKE21 (DHI, 2022) and TUFLOW (BMT, 2020) that do not

619    have the capability for representing partially flooded cells.

620  The LSG models improve predictions significantly compared to using a low-fidelity

621  model. The low-fidelity model overpredicts the inundation extent compared to the high-

622  fidelity model, which is consistent with the degree of overprediction of water depths shown

623  in Figure 7. This was expected of the low-fidelity model, as coarser grids tend to exhibit

624  larger dispersion of the flood inundation extents (Chatterjee et al., 2008; Yu & Lane, 2006).

625  For inundation extents below approximately 300 km², the predicted inundation extent

626  spuriously fluctuates for both the LSG-WD (Weighted) and LSG-WD (Unweighted) models,

627  resulting in uncertain predictions. This is due to the threshold applied for converting the data

628  to binary values. At low water depths, the entire cell can quickly change between flooded and

629  dry, and this means that large areas can suddenly transition from a dry to a flooded state and

630  vice versa. The predictions of the LSG-EXT (Weighted) model are less variable as the

631  distinction between flooded and dry areas is already incorporated in the setup and training of

632  the model.
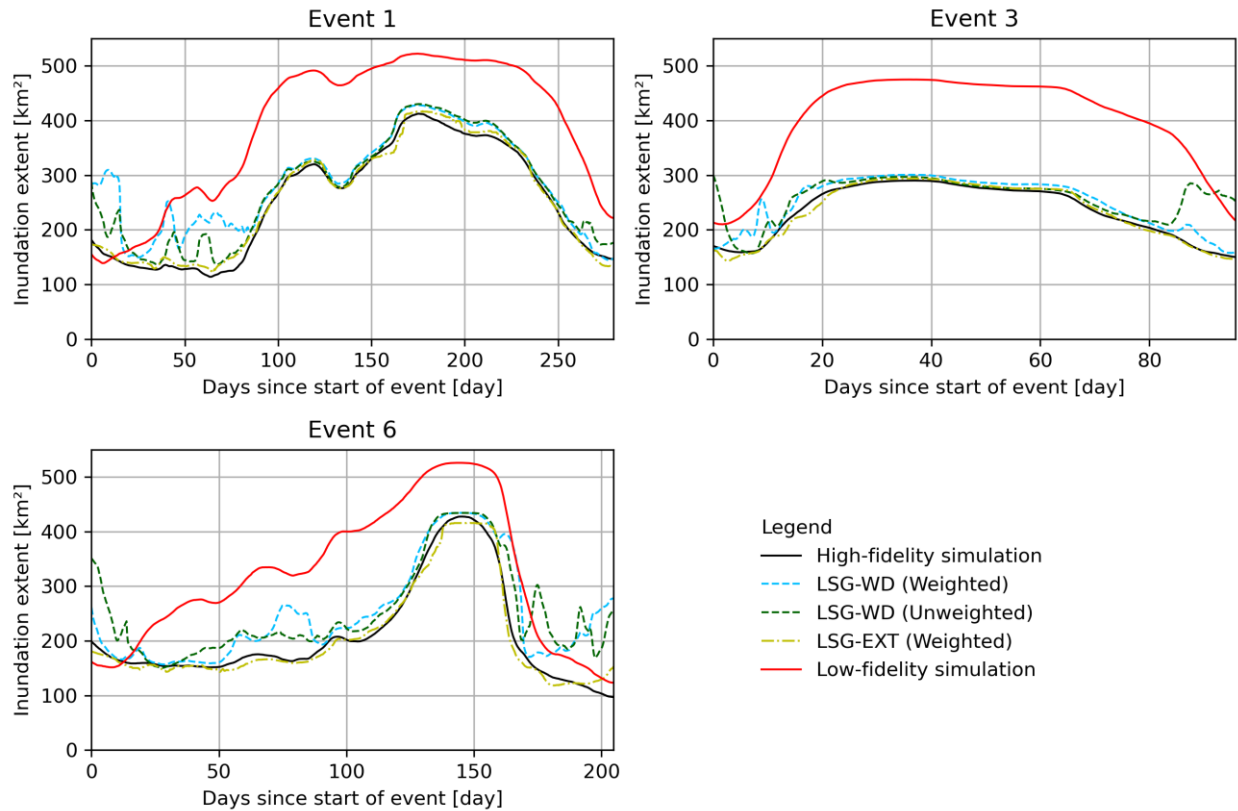

633

634

635

636

**Figure 8: Inundation extent using the high-fidelity, low-fidelity, LSG-WD (Weighted), LSG-WD (Unweighted) and LSG-EXT (Weighted) models for three representative events 1, 3, and 6. The predicted inundation extents for the remaining events are included in the supporting information.**

The relRMSE, relPeakValErr and relPeakTimeErr evaluation metrics are displayed in Table 1. With reference to the relRMSE metric, the LSG-EXT (Weighted) model performs the best and has errors consistent with the values reported in Fraehr et al. (2022). Of the LSG-WD (Weighted) and (Unweighted) models, the performance is similar although the unweighted model has a lower standard deviation.

With reference to the relPeakValErr metric, the LSG-EXT (Weighted) model still outperforms the water depth-based models. Another interesting observation is that the LSG-WD (Weighted) and (Unweighted) models generally overpredict the peaks, whereas the LSG-EXT model underpredicts the peaks.

For the timing of the peaks, all the models provide predictions that are generally late compared to the high-fidelity model. The low-fidelity model shows the lowest mean timing error, although the LSG-EXT (Weighted) perform almost equally well to the low-fidelity model and has a lower standard deviation. All the models show a relatively high standard

655    deviation for the relPeakTimeErr compared to the other metrics, thus indicating a large

656    uncertainty. This is due to the flat topography of the Chowilla floodplain and the low gradient

657    of the Murray River, resulting in flood events with long-lasting flat attenuated peaks, where

658    minor uncertainties in the predictions can have a large influence on the exact timing of the

659    peak. This is also evident in Figure 8, where the temporal evolution of the inundation extents

660    of all the LSG models follows the high-fidelity model well in the vicinity of the peak. In

661    addition, it might be expected that using an increasingly coarser low-fidelity model will result

662    in the LSG models predicting consistently early peak timings due to the larger dispersion of

663    the flood extent. However, this is not evident from the results, even though this study uses a

664    low-fidelity model that is much coarser than that used in Fraehr et al. (2022).
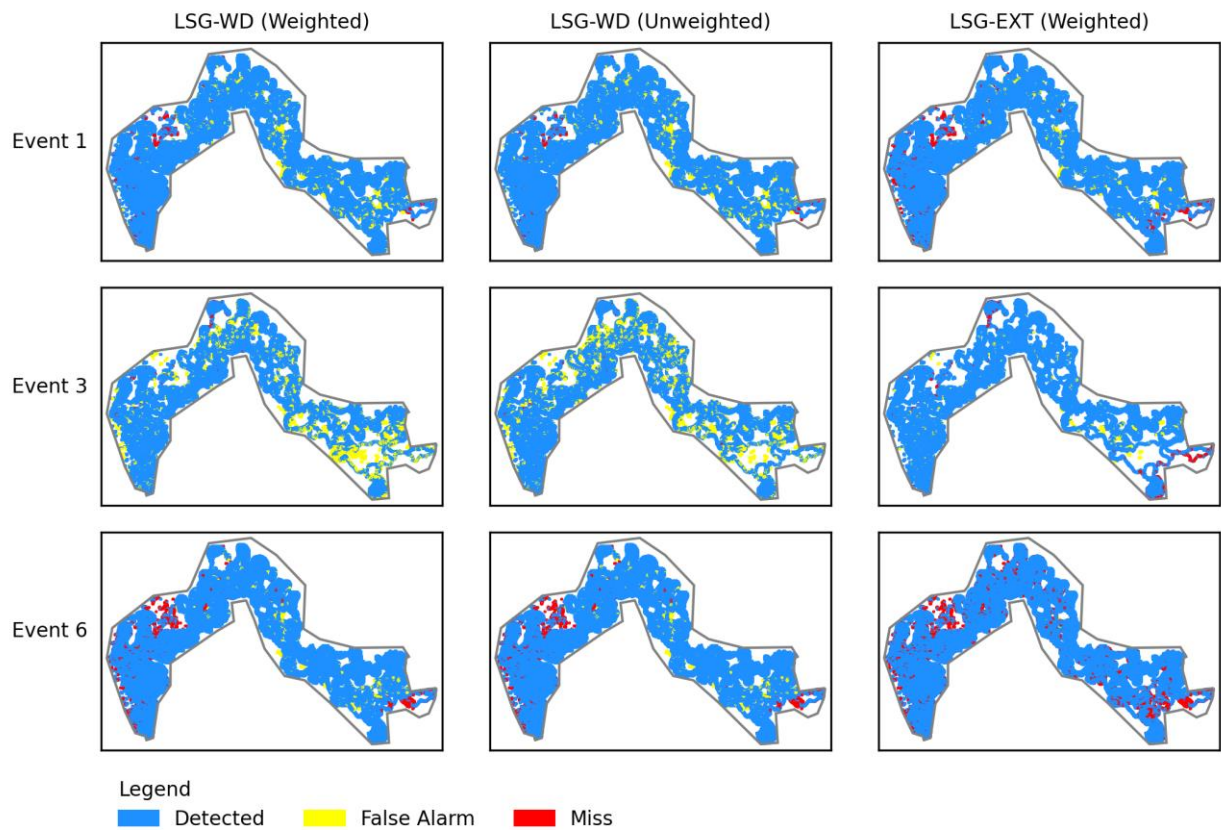

665        The POD, RFA and CSI metrics measure the LSG models' ability to predict the

666    spatial coverage of the maximum inundation extent. In Table 1, the LSG-EXT (Weighted)

667    model has a lower POD and RFA than the LSG-WD (Weighted) and (Unweighted) models.

668    This is due to the LSG-EXT model's general underprediction of the flood extent. The LSG-

669    WD (Weighted) and (Unweighted) models generally overpredict the inundation extent and

670    therefore they have a high probability of detecting a flooded area, but also a higher rate of

671    false alarms. Considering the CSI, the LSG-WD (Weighted) performs better than the LSG-

672    WD (Unweighted). This is surprising as the LSG-WD (Unweighted) shows better

673    performance for the temporal evolution of the flood extent measured by relRMSE,

674    relPeakValErr and relPeakTimeErr. Although the results are similar, this suggests that

675    weighting slightly improves the LSG model's ability to correctly identify the spatial coverage

676    of the maximum inundation extent.

692

693 The maximum inundation extent for the LSG models is shown in Figure 9 for three

694 representative events. The results for the low-fidelity model are not shown due to the large

695 overprediction of the low-fidelity model. The LSG-WD (Weighted) and (Unweighted)

696 models both over- and underpredict the inundation extent, as indicated by the misses and

697 false alarms. The largest difference between the models is evident for the (smaller) event 3,

698 where the LSG-WD (Unweighted) model significantly overpredicts the inundation and the

699 LSG-EXT (Weighted) model performs well with only minor areas of misses and false alarms.

700 The LSG-WD (Weighted) model achieves a performance that lies between the two other

701 models for event 3.

702

5.3 Additional results

5.3.1 Comparison of EOF analysis for each LSG model

A different number of significant modes have been found in the EOF analyses undertaken for each of the three LSG models (LSG-WD (Weighted), LSG-WD (Unweighted) and LSG-EXT (Weighted)), as shown in Table 2. Individual EOF analyses have been performed for the training data used in each fold of the cross-validation (See section 4.3), resulting in a total of ten EOF analyses for each LSG model. The number of significant modes in each EOF analysis is found through North's test and Kaiser's rule, as described in section 2.1.3.

The LSG-WD (Unweighted) tends to have the least number of significant modes. This is noteworthy as a model with fewer modes implies a lower degree of dimensionality to

719  explain the majority of variance in the dataset, and this has the benefit of requiring fewer

720  features to be predicted using the Sparse GP model. Furthermore, the proportion of variance

721  explained when performing EOF analysis on binary values in the LSG-EXT (Weighted)

722  model is lower than the water-based LSG models, even though a similar number of

723  significant modes are found. The reason for this is found in the methodology of the EOF

724  analysis. The EOF analysis seeks to find a linear combination of ECs and EOFs to maximize

725  the variance. Linear combinations of continuous values reconstruct poorly when predicting

726  binary data, and therefore more modes are needed to explain the variance. Another way to

727  think about this is in terms of variance between the cells. In the binary dataset, one cell might

728  be dry and another flooded, and therefore the values switch between 0 and 1. However, in the

729  water depth-based datasets, the same two cells might have a water depth of 0.00 m and 0.05

730  m, respectively, and thus the numerical difference is smaller when using water depths. This

731  also explains why the LSG-WD (Weighted) model needs more modes than the LSG-WD

732  (Unweighted) model, as some of the cells might have a higher weight, and the water depth

733  thereby is multiplied by a large value, creating a big difference in values between the cells.

734  **Table 2: Significant modes and explained variance from the EOF analyses for each LSG**

735  **model. Results are shown as means with the standard variation shown in parentheses of**

736  **the EOF analyses performed for the 10-fold cross-validation.**

| LSG model | Number of significant modes | Variance explained |
|---|---|---|
| LSG-WD (Weighted) | 42 (18) | 99.7 (0.2) % |
| LSG-WD (Unweighted) | 32 (9) | 99.7 (0.3) % |
| LSG-EXT (Weighted) | 37 (12) | 90.6 (1.8) % |

737

738  5.3.2 Computational efficiency

739      The simulations using the low- and high-fidelity models, as well as the EOF analyses

740  and the model training and prediction steps with the Sparse GP models, have all been

741  undertaken on a high-performance computer with a 3.70 GHz processor with Intel® Xeon®

742  E-2288G CPU, 64 GB ram, 64 cores and a NVIDIA Quadro RTX 5000 graphic card. The

743  simulations in HEC-RAS were undertaken using the "All available cores" option, which was

744  found to be the most computationally efficient setting in the initial testing.

745    The computational times using the different models have been summarised in Table 3

746    for event 3. The tendency is similar for the other events. The advantage of using the LSG

747    methodology over the high-fidelity model is clear, as the computational time is

748    approximately 12 times faster. The time for training and prediction using the three versions of

749    the LSG model varies. This is due to a different number of Sparse GP models being trained,

750    because of a different number of significant modes found in the EOF analysis (See section

751    5.3). When using event 3 for validation, a total of 75, 37 and 23 significant modes were found

752    in the EOF analysis for the LSG-WD (Weighted), LSG-WD (Unweighted), and LSG-EXT

753    (Weighted) models, respectively. If the LSG models all had an equal number of significant

754    modes and thereby Sparse GP models, the training and prediction times would be similar.

755    The difference in prediction time between the low-fidelity model and the LSG models is the

756    prediction time of the Sparse GP models and the subsequent reconstruction of the inundation

757    dataset. This time is minimal compared to the low-fidelity simulation time. As the low-

758    fidelity model needs to be run every time a prediction is required using the LSG

759    methodology, it is worth further exploring the possibilities of further enhancing the efficiency

760    of the low-fidelity model.

761    Another aspect when considering using the LSG model is the time used for the

762    creation of the training dataset in Step 1 of the model setup (see section 2.1.1). In the training

763    dataset development, numerous simulations of both the low- and high-fidelity models are

764    needed. In this study, a total of 29 events were simulated. This required approximately 24

765    computational days for the high-fidelity model and represents a large computational burden

766    that needs to be overcome before the LSG model can be implemented. However, the training

767    dataset generation only needs to be undertaken once before being used to provide predictions,

768    whereafter the full speed of the LSG model can be utilised.

769

775

**6 Discussion**

776

777        This study demonstrates that the LSG model is a powerful tool to upskill low-fidelity
778 model simulations to emulate the results of a fully 2D hydrodynamic high-fidelity model on
779 an unstructured grid. In this section, we discuss several points, including the importance of
780 weighting according to grid cell size, the best method for predicting flood extent, and the
781 future directions for the LSG model.

782 6.1 Importance of weighting in EOF analysis

783        Two water depth-based versions of the LSG model are explored in this study, one
784 with weighting according to cell size before the EOF analysis (i.e. the LSG-WD (Weighted)
785 model) and one without weighting (i.e. the LSG-WD (Unweighted) model). The purpose of
786 the development of these models was to examine the value of using weights to compensate
787 for the varying grid cell sizes in an unstructured grid. It was found that the water depth
788 predictions for the two models are similar, and this suggests that weighting is of minor
789 importance when applying the LSG model to simulate flood inundation on an unstructured
790 grid. The predicted inundation extent using the two models is also similar. For the evolution
791 of the total inundation extent the LSG-WD (Unweighted) model shows better performance
792 than LSG-WD (Weighted) as seen by the relRMSE, relPeakValErr and relPeakTimeErr being
793 closer to 0. However, the relRMSE, relPeakValErr and relPeakTimeErr consider the
794 summarised area and not the spatial location of the inundation. Correctly capturing flooded
795 areas is of high importance for flood risk assessments. The LSG-WD (Weighted) model has a
796 CSI closer to 1, and thus, more accurately captures the spatial coverage of the inundation.

797    Although the difference is minimal, this suggests that the weighting helps the LSG model to

798    more correctly identify the dry and flooded areas. The reason for improved accuracy when

799    weighting is applied is possibly due to the nature of the EOF analysis. The EOF analysis is a

800    measure of variability and treats all cells equally, thus assuming equal spacing and size. The

801    weighting is a way of counteracting the uniform influence of the individual grid cells and

802    creates what is known as "intrinsic EOFs" (Baldwin et al., 2009; North et al., 1982). Intrinsic

803    EOFs are continuous spatial fields independent of the grid. Based on the results of POD, RFA

804    and CSI, creating these more generalised EOF spatial fields seem to better compensate for the

805    reduced accuracy of the coarser low-fidelity model.

806         Both water depth-based LSG models show spurious fluctuations in the predicted

807    inundation extent for areas below 300 km². The inundation extent for the LSG-WD

808    (Weighted) and LSG-WD (Unweighted) adopts a 3 cm water depth threshold to convert the

809    results to binary values. This threshold was chosen to make the method and results

810    comparable to the previous study by Fraehr et al. (2022) where a MIKE21 model was used.

811    However, as mentioned in section 5.2, HEC-RAS can accommodate partially flooded cells

812    due to a subgrid treatment that accounts for the terrain variations within a cell. This capability

813    has been tested to convert the water depths to a partially flooded cell area (see supporting

814    information). The use of this option improves predictions significantly and remediates the

815    spurious fluctuations evident in Figure 8 for the predicted inundation extents below 300 km²

816    for both the LSG-WD (Weighted) and LSG-WD (Unweighted) models. However, using

817    partially flooded cells is only possible when using hydrodynamic models that have subgrid

818    solvers, such as HEC-RAS, and for that reason, it is not used for comparisons in this study.

819         Weighting according to grid cell size is simple, easy to implement and commonly

820    used (Baldwin et al., 2009; Hannachi et al., 2007), though the results of this study show that

821    applying this weighting scheme has minimal effect on the accuracy of the LSG model. Due to

822    the simplistic nature of the weighting scheme applied, it is worth considering if a more

823    sophisticated weighting scheme could increase the accuracy of the LSG model. However, as

824    the accuracy of the LSG model is already high, it is likely that only minor improvements

825    could be achieved; given the expected low return on effort (at least with this model

826    configuration), it was decided to forego investing effort in developing a more sophisticated

827    weighting scheme.

6.2 Flood extent derived from water depth predictions compared to a direct extent prediction

The LSG-EXT (Weighted) model for direct extent prediction proposed by Fraehr et al. (2022) is significantly better for predicting the inundation extent than the water depth-based LSG model, as shown by the evaluation metrics in Table 1. As discussed in the previous section, the water depth-based LSG models adopt a 3 cm threshold to differentiate between flooded and dry areas and minor numerical differences may determine whether a cell is flooded or not. If the water depth in a cell is 4 cm, the water depth-based LSG models are only allowed a numerical error of 0.01 before the cell is predicted as dry. On the other hand, the LSG-EXT (Weighted) model predicts values between 0 and 1, with a threshold of 0.5 for flooding and drying. Thus, the LSG-EXT (Weighted) model accommodates larger numerical errors without it affecting the predicted inundation extent.

However, information on water depth is highly beneficial for risk assessments and can greatly assist in the identification of flood hazards. Flood inundation predictions should therefore be carried out using both an extent- and water depth-based LSG model. The extent-based LSG model should be used to predict the inundation extent, and the water depth-based LSG model should then be used to predict the water depth for those areas predicted as being flooded. The accuracy of the inundation extent estimates would be similar to the performance of the LSG-EXT (Weighted) model, and the water depth predictions would be similar to the LSG-WD (Weighted) model. Accordingly, these results are not shown here, but this approach is recommended for future implementations of the LSG model.

6.3 Future directions for the LSG model

The low-fidelity model used in this study is approximately 12 times faster than running a high-fidelity model. This is a substantial improvement in computational efficiency. However, in ensemble modelling used for risk assessment hundreds or thousands of model runs are needed (Nayak et al., 2018; Nester et al., 2012; Wu et al., 2020). Ensemble modelling would help uncover if the errors in the LSG model predictions are lower than the uncertainty associated with the input boundaries. This would improve the confidence in using the LSG model as the LSG model would not be the biggest source of uncertainty in the inundation predictions.

Ensemble modelling imposes a high computational demand on the low-fidelity model, and therefore, further research into optimising the efficiency of the low-fidelity model is needed. Options for improving the computational efficiency include simplifying the geometry

860    by using still coarser grid cells, increasing the timestep, reducing model complexity by

861    adopting simplifying assumptions, or using a more computationally efficient model or

862    software (Razavi et al., 2012). HEC-RAS is currently the only hydrodynamic modelling

863    software that utilises subgrid treatment on an unstructured grid and for that reason was

864    chosen in this study. As an example of other models to use, the LISFLOOD-FP model

865    proposed by Bates and De Roo (2000) has been shown to be 20 times faster than HEC-RAS

866    when running both models on the same grid and timestep (Shustikova et al., 2019). This

867    suggests that LISFLOOD-FP may provide fast low-fidelity flood inundation estimates,

868    although LISFLOOD-FP predicts flood inundation on a quadratic grid and does not have the

869    same subgrid treatment as included in HEC-RAS, which might reduce its accuracy. Future

870    studies should explore using other modelling software to examine the accuracy and

871    computational efficiency of the LSG model across a variety of hydrodynamic modelling

872    platforms.

873          Besides the computational efficiency of the LSG model, the low-fidelity model also

874    affects the accuracy. Minimal attention has been given to the accuracy of the low-fidelity

875    model in the development of the LSG model in both this study and the previous study by

876    Fraehr et al. (2022),. Considering the RMSE of the LSG models in Figure 5, the highest

877    errors are located in a few local areas. This suggests that performance in these areas might be

878    improved by locally improving the low-fidelity model. Another consideration is to calibrate

879    the low-fidelity model using observations and/or the results of the high-fidelity model as this

880    to some degree can counteract the dispersion of the flood inundation due to the coarser grid

881    (Yu & Lane, 2006). In locations with available and regularly updated observations, it may be

882    expected that the use of data assimilation could improve the accuracy of the LSG model

883    (Jafarzadegan et al., 2021). Only a few studies have explored the use of data assimilation in

884    combination with hydrodynamic models. For example, Xu et al. (2017) used data

885    assimilation together with a 1D river model, and Jafarzadegan et al. (2021) used data

886    assimilation together with a 2D flood inundation model with a coarse 120 m rectangular grid.

887    Accordingly, incorporating data assimilation in the LSG model could provide accurate

888    predictions in high resolution for future real-time forecasting applications. Future studies

889    should therefore focus on improving the precision of the LSG model, as well as on increasing

890    computational efficiency.

891          Data-driven models like the Sparse GP model are particularly good at describing

892    complex non-linear relationships, such as those between the low- and high-fidelity ECs. In

893    the initial tests, other data-driven models like the Multilayer Perceptron have been tested and

894    shown to have similar performance to the Sparse GP model, although the Multilayer

895    Perceptron did not provide an uncertainty estimate. Similarly, Carreau and Guinot (2021)

896    used a simple Artificial Neural Network (ANN) structure in their study to describe the

897    relationship between ECs. The LSG model is therefore not limited to using the Sparse GP

898    model, and other data-driven could be implemented.

899    The LSG model needs to be tested on other types of flooding behaviour to ensure that

900    the prediction accuracy of the LSG model is robust. This could include consideration of

901    storm surge flooding in an estuary, urban flooding, and compound floods resulting from

902    exogenous influences. Future applications will further examine the capabilities of the LSG

903    model and help ensure it is a robust surrogate model for flood inundation.

904    **7 Conclusion**

905    Flood inundation is a major cause of hazards to infrastructure and people.

906    Traditionally flood inundation is predicted using high-fidelity models that are accurate, but

907    computationally expensive to apply. In a previous study, the hybrid LSG model has been

908    proposed to predict the dynamic behaviour of the flood inundation extent in a more

909    computationally efficient way than the traditional high-fidelity models. This study shows how

910    the LSG model can be further developed to predict the water depth of the inundation, as well

911    as the extent.

912    The LSG model uses a low-fidelity model to transform the boundary input spatially

913    and temporally by simulating the flood inundation on a coarse computational grid. The

914    inundation simulations are then decomposed using EOF analysis to a set of key features.

915    After initial training, a Sparse GP model converts the key low-fidelity features to high-

916    fidelity features. Using the predicted high-fidelity features to reconstruct the inundation thus

917    enables the LSG model to predict the flood inundation with a similar level of accuracy as a

918    high-fidelity model, but without the computational burden involved.

919    The LSG model is evaluated by simulating flood inundation for the Chowilla

920    floodplain using a HEC-RAS model with an unstructured grid. The LSG model is

921    approximately 12 times faster than using a high-fidelity model and provides accurate

922    predictions of the flood inundation depth and extent. In comparison to the high-fidelity

923    model, the LSG model has a RMSE with a mean of 4 cm and a standard deviation of 5 cm for

924    the water depth predictions. The larger errors are concentrated in local areas and could

925    potentially be resolved by locally improving and/or calibrating the low-fidelity model.

926        To compare the LSG model for water depth prediction to the previous LSG model

927    developed for direct flood extent predictions, both models were used to simulate the flood

928    inundation of the Chowilla floodplain. The extent-based model exhibits significantly better

929    separation of dry and flooded areas. However, including water depth in the inundation

930    predictions have considerable potential to improve flood risk assessments. For that reason,

931    using both an extent- and water depth-based LSG model should be explored as a strategy to

932    ensure high accuracy of both the inundation extent and water depth.

933        When applying the LSG model as a surrogate for a high-fidelity model with an

934    unstructured grid, the different grid cell sizes are incorporated by weighting according to the

935    cell area in the EOF analysis. To explore the importance of this weighting, two LSG models

936    with and without weighting were developed. The results indicate that the weighting has

937    minimal influence on the water depth predictions, though the weighting does show minor

938    improvements in the LSG model's ability to correctly predict the spatial locations affected by

939    the inundation. It is therefore recommended to apply a weighting based on cell areas when

940    applying the water depth based LSG model for predicting flood inundation on an

941    unstructured grid.

942        Future studies of the LSG model should focus on the low-fidelity model development.

943    The low-fidelity model is the most computationally demanding part of the LSG structure, and

944    it has a great influence on prediction accuracy. Optimising the low-fidelity model can

945    therefore significantly influence the performance of the LSG model. In addition, it would be

946    of interest to test the LSG model on a wide range of flood problems to evaluate the benefits

947    of the approach in more detail.

948

954

**Open Research**

The LSG model is coded using Python (Version 3.9) and is available in Fraehr (2023) together with the data used to produce the results in this paper.
