21 **Key Points:**

22 • The latent heat transport of the monsoon systems increases through higher CO$_2$
23   concentration, but it is reduced by the Eocene topography.

24 • The poleward heat transport of midlatitude cyclones is higher in the Northern
25   Hemisphere in the Eocene, due to the different topography.

26 • The Hadley cells are overturning more heat in response to the higher CO$_2$ values, but the
27   net poleward heat transport is relatively stable.

28
29

30   **Abstract**

31   The total meridional heat transport (MHT) is relatively stable across different climates.
32   Nevertheless, the strength of individual processes contributing to the total transport are not
33   stable. Here we investigate the MHT and its main components especially in the atmosphere, in
34   five coupled climate model simulations from the Deep-Time Model Intercomparison Project
35   (DeepMIP). These simulations target the Early Eocene Climatic Optimum (EECO), a geological
36   time period with high CO_2 concentrations, analogous to the upper range of end-of-century CO_2
37   projections. Preindustrial and early Eocene simulations at a range of CO_2 levels (1x, 3x and 6x
38   preindustrial values) are used to quantify the MHT changes in response to both CO_2 and non-
39   CO_2 related forcings. We found that atmospheric poleward heat transport increases with CO_2,
40   while the effect of non-CO_2 boundary conditions (e.g., paleogeography, land ice, vegetation) is
41   causing more poleward atmospheric heat transport on the Northern and less on the Southern
42   Hemisphere. The changes in paleogeography increase the heat transport via transient eddies at
43   the mid-latitudes in the Eocene. The Hadley cells have an asymmetric response to both the CO_2
44   and non-CO_2 constraints. The poleward latent heat transport of monsoon systems increases with
45   rising CO_2 concentrations, but this effect is offset by the Eocene topography. Our results show
46   that the changes in the monsoon systems' latent heat transport is a robust feature of CO_2
47   warming, which is in line with the currently observed precipitation increase of present day
48   monsoon systems.

49

50   Plain Language Summary

51   In the Earth's climate system both the atmosphere and the ocean are transporting heat
52   through different processes from the tropics towards the poles. We investigate the transport of
53   the atmosphere in several climate model set ups, which are aiming to describe the very warm
54   climate of the early Eocene (~56-48 Myr ago). This period is relevant for us, because the
55   atmospheric CO_2 concentration was close to our pessimistic projection of CO_2 concentration for
56   the end of the century. In our study we are separating the results depending on their origin,
57   meaning if the changes, seen in the heat transport are due to the larger CO_2 concentration or due
58   to the different set up of the Eocene. We found that with rising CO_2 values the atmosphere
59   transports more heat from the tropics to the polar regions. The different location of the continents
60   and seas is influencing the heat transport of the midlatitude cyclones. The monsoon systems
61   seem to be affecting a globally smaller area in the Eocene, but being more effective in
62   transporting heat due to the higher atmospheric CO_2 concentration. This conclusion is in line
63   with the observation, that current day monsoon systems' precipitation increases, as our CO_2
64   concentration rises.

65

66   **1 Introduction**

67   The meridional temperature gradient is the main driving force of the atmospheric and
68   oceanic general circulation. It is caused by differential radiative heating and leads to meridional
69   heat transport from the tropics to the mid- and high latitudes. It has been shown that the
70   Meridional Heat Transport (MHT) is stable in different climate states (Krapp & Jungclaus, 2011;
71   Smith et al., 2006; Yang et al., 2015). Bjerknes (1964) proposed that if the net radiation forcing
72   at the top of the atmosphere (TOA) and the ocean heat storage do not vary too much, then the

73   MHT shall be also relatively stable. This leads to the expectation that any large variations in heat
74   transport in the atmosphere and in the ocean should be equal in magnitude and opposite in sign,
75   nevertheless it does not rule out large changes in both ocean and atmosphere. This mechanism
76   since have been known as the Bjerknes compensation (BJC). Stone (1978) later showed that the
77   MHT is mainly determined by the solar constant, the axial tilt, the radius of the Earth and the
78   mean planetary albedo. Among these variables only the albedo is an internal parameter of the
79   atmosphere-ocean system, and it highly depends on temperature, as a defining factor on clouds,
80   ice and snow. Different modelling studies suggest that the BJC is valid in different paleo climate
81   states, for example during the glacial-interglacial period of the last 22 000 years (Yang et al.,
82   2015), or in the warm climate of the Middle Miocene (Krapp & Jungclaus, 2011). Also, it was
83   found in preindustrial and in historical simulations of CMIP5 models, where in the latter, the
84   climate is not in equilibrium and external forcings are present (Outten et al., 2018). Even in
85   extreme theoretical cases, such as the aqua-planet, BJC is shown to be valid (Smith et al., 2006).

86   Even though total MHT is stable in different climate states, the contributions from
87   various transport processes might change. Quantifying transport processes is a great tool to
88   identify the large scale features of different climate states and reveal any compensating
89   mechanism. In the climate system the heat is transported by the atmosphere and the ocean via
90   different mechanisms. In the tropical belt both the atmosphere and the ocean contribute to the
91   MHT equally, while at higher latitudes the atmospheric transport dominates (Masuda, 1988). At
92   lower latitudes the heat is transported mainly by the meridional overturning circulation (MOC),
93   which is represented by the Hadley cell in the atmosphere and by the wind-driven gyres in the
94   upper ~1000 m of the ocean (Held, 2001). Note that we do not evaluate separately the role of the
95   ocean's meridional overturning circulation so that MOC hereafter refers always to the
96   atmosphere in this study. At higher latitudes the heat is transported dominantly by the
97   atmosphere via different eddies, such as transient eddies (TE), comprised mainly of mid-latitude
98   cyclones, and stationary eddies (SE), which represent monsoons in the subtropics and planetary
99   waves in midlatitudes. The stationary planetary waves are connected to diverse topography and
100   land-sea thermal contrast (Wills et al., 2019).

101   Change in the different transport processes have been shown to be relevant in the present
102   climate, for example the changes in the poleward atmospheric and oceanic heat transport has
103   been shown to contribute to the polar amplification (Forster et al., 2021). In a warmer climate the
104   equator-to-pole gradient of atmospheric moisture is expected to increase due to the exponentially
105   increasing water holding capacity of warmer air. The larger moisture gradient enhances the
106   poleward latent heat transport. This process plays an important role in polar amplification. The
107   polar amplification on the other hand results in a weakening of the equator-to-pole temperature
108   gradient, which decreases the dry-static energy transport, what in turn partly compensates the
109   increase in latent heat transport (Forster et al., 2021).The latest IPCC report shows that in our
110   current warming climate large scale circulation patterns such as the Hadley cell or the monsoon
111   systems have been changing (Gulev et al., 2021). Regarding the Hadley circulation the studies
112   mostly indicate changes in the northern Hadley cell, in the form of widening and strengthening
113   of the circulation (Gulev et al., 2021). The North Hemisphere summer monsoon precipitation
114   shows an increase in the recent past (Gulev et al., 2021).

115   Investigating the large scale circulation trough, the transport processes in a past warm
116   period of Earth's climate system can help to better understand our future in a warmer climate.
117   Paleoclimate model simulations in contrast to future projections, have the advantage, that there

118   are proxy data available, which help to validate the model's response to any changes in the
119   forcing. Proxies help reducing the uncertainties, when modelling a climate state in extreme
120   circumstances. One of the best examples of past warm periods is the Early Eocene Climatic
121   Optimum (EECO, ~56-48 Myr ago). It is the period of greatest sustained (> 1 Myr) warmth in
122   the last 65 million years (Lunt et al., 2017) ,when CO_2 concentrations are estimated to have
123   fallen between 1170 and 2490 ppm (Anagnostou et al., 2020) and the estimated global mean
124   surface temperatures reached 27.0 °C (23.2 to 29.7 °C), approximately 10 to 16 °C warmer than
125   preindustrial climate (Inglis et al., 2020). It has been shown (Evans et al., 2018), that the
126   meridional temperature gradient was much weaker in the Eocene's warm climate than at present,
127   thus indicating strong polar amplification, which is a challenge to capture for most climate
128   models. There has been a community effort in creating a framework for the intermodel
129   comparison of Paleocene-Eocene simulations (Lunt et al., 2017) and also to coordinate the
130   methodology of a proxy data compilation focusing on temperature and CO_2 concentrations from
131   this period (Hollis et al., 2019). This coordinated effort is the Deep Time Model Intercomparison
132   Project (DeepMIP), and the time intervals its focusing on are the latest Paleocene (pre-PETM),
133   Paleocene–Eocene thermal maximum (PETM) and early Eocene climatic optimum (EECO). In
134   DeepMIP, the atmospheric CO_2 concentrations and other boundary conditions, such as the
135   paleogeography, orbital configurations, solar constant, vegetation, and lack of continental ice
136   sheets were uniformly defined. Eight modelling groups participated in performing paleo
137   simulations, with the agreed boundary conditions. Some models are closer to the proxy records
138   than others, but all simulations indicate a warmer, than present day global mean temperature and
139   a smaller, than present day meridional SST gradient. The Community Earth System Model
140   (CESM), the Geophysical Fluid Dynamics Laboratory model (GFDL) and the Norwegian Earth
141   System Model (NorESM) perform well in simulating the global mean temperature and
142   meridional SST gradient at CO_2 levels, which are also in the proxy indicated range (Lunt et al.,
143   2021). The closest agreement with proxy data is found for simulations at 6x times the
144   preindustrial CO_2 concentration, which also aligns with the best-estimate of CO_2 signal from
145   proxy data. In terms of simulating the lowest meridional temperature gradient the most
146   successful simulation is from CESM (Lunt et al., 2021).

147   Several studies have investigated the EECO's heat transport with the intention to explain
148   its low temperature gradient. Increased heat transport, especially increased ocean transport have
149   been suggested to be the mechanism responsible for the low meridional gradient (Barron, 1987;
150   Sloan et al., 1995). It has been estimated that 30% or even greater increase in poleward heat
151   transport, than at present is needed to achieve the low temperature gradient of Eocene (Huber &
152   Nof, 2006; Sloan et al., 1995). This is problematic, since we do not know any acceptable
153   mechanism to realize such a large transport change, neither is it something any respective
154   modelling study would have indicated. The Eocene meridional heat transport have been studied
155   with coupled global circulation models (Heinemann et al., 2009; Huber & Sloan, 2001), and
156   their results support the notion that not the increased oceanic heat transport is the responsible
157   mechanism for the low meridional temperature gradient.

158   In our work we focus on the changes in the different atmospheric transport processes in
159   the EECO, to better understand the atmospheric large scale circulation pattern of this warm
160   climate. Moreover, we separate these changes depending on their underlying causes, namely if
161   they are driven by the CO_2 increase or the non-CO_2 forcing of the paleo simulations. We
162   compare the results of five different models from the DeepMIP ensemble. Dividing the changes
163   into non-CO_2 and CO_2 forcing helps us to also assess the relevance of the results for future

164 climate scenarios, where the CO_2-driven processes become more relevant than any changes in
165 topography. Our study aims to answer the following questions:

166 • Can the DeepMIP model ensemble capture the characteristics of transport processes in
167   the preindustrial control (PI) simulations?

168 • What are the impacts of changes of non-CO_2 constraints (paleogeography, vegetation, no
169   continental ice sheet) on the different atmospheric transport processes?

170 • What are the impacts of CO_2 concentration increase on the atmospheric transport
171   processes in the 3x and 6x CO_2 EECO simulations?

172 • How does the overall change (non-CO_2 and CO_2 constraints) between the preindustrial
173   control and EECO simulations look like? Which physical transport processes are affected
174   the most?

175   The paper is structured as follows, in section 2 we briefly introduce the DeepMIP
176 experimental design, the selected models and reanalysis, and we explain the methods used in the
177 analysis. Then the results section shows the transport changes due to the non-CO_2 and the CO_2
178 constraints, first individually and then their combined effect on changes between past and present
179 climates. Then section 4 discusses the three large scale circulation patterns, which are affected by
180 either one or both of the CO_2 and non-CO_2 constraints. In section 5 we summarize our findings
181 and conclude.

182   **2 Data and Methods**

183   In this study we analyze climate model simulations from DeepMIP simulations. We
184 further include present day data from the ERA5 reanalysis to compare it with the respective
185 preindustrial simulations of the DeepMIP models.

186   2.1 Experimental design

187   The experimental design and the different models included in DeepMIP are described in
188 Lunt et al. (2017, 2021), here we only introduce them briefly. DeepMIP was conducted to offer a
189 consistent framework for climate model simulations of three warm periods in the latest
190 Paleocene and early Eocene (~ 55 to ~ 50 Ma), which are the Early Eocene Climatic Optimum
191 (EECO), the Paleocene–Eocene Thermal Maximum (PETM) and the period just before the
192 PETM (pre-PETM). These time periods of Earth's climate are characterized by high atmospheric
193 CO2 concentrations estimated to be between 800 and 3160 ppm (Anagnostou et al., 2020), which
194 means at least 3x higher concentrations than the preindustrial value (280 ppm) and almost 12x
195 more at its highest. The concentrations during the EECO, which is the longest of the three, is
196 estimated to fall between 1170 and 2490 ppm. This is around 4x and 9x the preindustrial
197 concentration level. Many DeepMIP groups performed multiple experiments at various CO_2
198 levels, for example at 1x, 3x, 6x or 9x the preindustrial CO_2 concentration, to capture this
199 uncertainty. Apart from the atmospheric CO_2 concentrations other boundary conditions, such as
200 the paleogeography, orbital configurations, solar constant, vegetation, continental ice sheets and
201 aerosols, are needed to be defined to set up a deep-time simulation. The paleogeography
202 represents the Ypresian stage of the Eocene, where the most notable differences to today's
203 geography are the lack of the Himalaya, the lack of the enclosed Mediterranean basin, the proto-
204 Paratethys and the Siberian Sea and a narrower Atlantic basin. The digital reconstruction from

205 Herold et al. (2014) is used for the paleogeography, vegetation, and river routing. The orbital
206 configuration is set to the modern values, because it represents a forcing close to the long-term
207 average (Lunt et al., 2017). Both the solar constant, and non-CO_2 greenhouse gas concentrations
208 are set to preindustrial values, to find a middle ground between the uncertainty on the increased
209 radiative forcing associated with enhanced non-CO_2 greenhouse gases and the decrease in
210 radiative forcing via a reduced solar constant (Lunt et al., 2017). One additional important initial
211 constraint is that there are no continental ice sheets in the Eocene simulations. Initial condition
212 for ocean temperature and salinity are given in Lunt et al. (2017) but each modeling group
213 followed their individual approach based on their previous paleo simulations or experiences with
214 model instabilities.

215 To accept a model simulation as the representation of the paleoclimate of EECO, PETM, or pre-
216 PETM it needs to be in (or close to) equilibrium. To assure this, three criteria are defined, the
217 first is regarding the length of the simulation (more than 1000 years) the second considers the
218 energy balance of the models (less than 0.3 W m−2 net radiation imbalance at the top of the
219 atmosphere or similar imbalance to that of the preindustrial control), and last is the test if the
220 ocean have reached its equilibrium state (sea-surface temperature trend is less than 0.1°C per
221 century in the global mean). These latter two shall be based on the final 100 years of the
222 simulation. Most of the simulations fulfill these conditions, and those which are not, only
223 overstep the thresholds slightly, thus Lunt et al. (2021) concluded them to be sufficiently
224 equilibrated.

225
226 **Table 1**
227 *List of models used in this study from the DeepMIP ensemble.*
228

Model (short name)	Experiments	Length of simulations (years)	Atmospheric resolutions (lat x lon)
CESM (**CESM1.2_CAM5**)	piControl 1x,3x,6x	2000	1.9° x 2.5°

GFDL (**GFDL_CM2.1**)	piControl 1x,3x,6x	6000	3° x 3.75°
HadCM3 (**HadCM3B_M2.1aN**)	piControl 1x,3x	7800	3.75° x 2.5°
MIROC (**MIROC4m**)	piControl 1x,3x	5000	2.79° x 2.81°

229

230

231   2.2 Models

232   In total 8 models participated in DeepMIP from which we selected 5, depending on the
233 available experiment types. In our study we focus on the CO_2 and non-CO_2 effects, thus we

234   needed from all models a preindustrial control simulation, a 1x CO_2 Eocene simulation, and also
235   at least one Eocene simulation with a higher CO_2 concentration. The three models, which we did
236   not include in our study (INMCM, IPSL, NorESM), are left out because there was no available
237   1x CO_2 simulation from them. We have chosen 3x and 6x CO_2 concentration simulations, where
238   they were available (see Table1). These concentrations, represent the pre-PETM and the
239   EECO/PETM conditions respectively. All models are coupled ocean-atmosphere models. The
240   selected simulations are summarized in Table 1. An overview of each model is listed below,
241   while the more elaborate description of the simulations and models are found in Lunt et al.
242   (2021) and in the corresponding papers.

243   CESM stands for the Community Earth System Model version 1.2, it consists of the
244   Community Atmosphere Model 5.3 (CAM), the Community Land Model 4.0 (CLM), the Parallel
245   Ocean Program 2 (POP), the Los Alamos sea ice model 4 (CICE), the River Transport Model
246   (RTM), and a coupler connecting them (Hurrell et al., 2013). The atmospheric part of the
247   coupled system has 30 hybrid sigma-pressure levels and a horizontal resolution of 1.9° × 2.5°
248   (latitude × longitude).The ocean and sea ice model use a nominal 1°x1° displaced pole
249   Greenland grid with 60 vertical levels in the ocean. Some modifications were needed to make the
250   Earth system model applicable for a paleoclimate simulation with a high CO_2 level applicable.
251   These effected the radiation parametrization, and the marginal sea balancing scheme. The ocean
252   was initialized from a previous PETM simulation (Kiehl & Shields, 2013) without any sea ice.
253   The simulations have been integrated for 2000 model years, except the 1xCO_2 simulation,
254   which has been integrated for 2600 model years.

255   COSMOS is developed at the Max Planck Institute for Meteorology and uses the
256   atmospheric general circulation model ECHAM5 (Roeckner et al., 2003) and the Max-Planck-
257   Institute for Meteorology Ocean Model (MPIOM) (Marsland et al., 2003) for the the ocean and
258   sea ice components. The atmospheric part has 19 vertical hybrid sigma-pressure levels and a
259   horizontal resolution approximately 3.75° × 3.75°. The ocean and sea ice dynamics are
260   calculated on a bipolar curvilinear model grid with formal resolution of 3.0° × 1.8° (longitude ×
261   latitude) and 40 unequal vertical levels. COSMOS' performance in paleoclimate studies is
262   described in Stepanek and Lohmann, (2012). The ocean was initialized with uniformly horizontal
263   and vertical temperatures of 10 °C in the 3×CO_2 concentration simulation and then the
264   simulations with 1 × and 4× CO_2 concentrations were restarted from 3×CO_2 after 1000 years.
265   The simulations were started with transient orbital configurations and were run for model year
266   8000, then they were run with preindustrial orbital parameters for the last 1500 years.

267   GFDL means the Geophysical Fluid Dynamics Laboratory (GFDL) CM2.1 model
268   (Delworth et al., 2006), with modifications to the late Eocene (Hutchinson et al., 2018, 2019).
269   The CM2.1 consists of Atmosphere Model 2, Land Model 2, the Sea Ice Simulator 1. The ocean
270   is calculated by the modular ocean model (MOM) version 5.1.0. The atmosphere has 24 vertical
271   levels and a horizontal resolution of 3° × 3.75°. The ocean and sea ice components are
272   calculated over 50 vertical levels with the horizontal resolution of 1◦ × 1.5◦ (latitude ×
273   longitude), and a tripolar grid is used as in Hutchinson et al. (2018). Due to the paleogeography
274   some manual adjustments were made in the ocean grid. The ocean temperature was initiated
275   from idealized conditions, similar to those outlined in Lunt et al. (2017). The simulations were
276   run for a total of 6000 years. During the initial 2000 years, two adjustments were performed on
277   the ocean temperature to accelerate the approach to equilibrium. This approach led to instabilities

278   at 6xCO2 level, this simulation was instead initialized using a globally uniform temperature of
279   19.32 °C and was run continuously for 6000 years.

280   HadCM3 is the abbreviation of the Hadley Centre Climate Model (Valdes et al., 2017).
281   The atmosphere has 19 vertical levels and a horizontal resolution of $3.7° \times 2.5°$, while the ocean
282   is calculated on a $1.25° \times 1.25°$ grid over 20 vertical levels. A few changes were necessary to
283   adapt the model to the deep-time simulations, such as a salinity flux correction, prognostic 1D
284   ozone scheme instead the fixed vertical profile, and also the disabling of modern-day specific
285   parametrizations, e.g., in the Mediterranean and the Hudson Bay. The ocean was initialized from
286   the final state of Eocene model simulations using lower resolution in the ocean, HadCM3L. The
287   HadCM3L simulations were initialized from a similar idealized temperature and salinity state as
288   described in Lunt et al., (2017). HadCM3 simulations were started from the respective
289   HadCM3L integrations after 4400 to 4900 years of spin up and run for a further 2950 years.

290   MIROC stands for Model for Interdisciplinary Research on Climate (Chan & Abe-Ouchi,
291   2020). The land surface model is the Minimal Advanced Treatments of Surface Interaction and
292   Runoff (MATSIRO) (Takata et al., 2003). The ocean component is the version 3.4 of the CCSR
293   (Center for Climate System Research) Ocean Component Model (COCO) (Hasumi, 2000). The
294   atmosphere has 20 vertical sigma levels and a horizontal resolution of approximately 2.79° x
295   2.81° (latitude x longitude).The ocean has 44 levels and a horizontal resolution is set to $256 \times$
296   196 (longitude $\times$ latitude), with a higher resolution in the tropics. The atmosphere is initialized
297   from a previous experiment without ice sheets and with a $\times 2$ CO2 concentration. The ocean is
298   initialized based on previous MIROC paleoclimate experiments and on the recommendations
299   from Lunt et al. (2017). For the experiments the model was run for 5000 model years.

300   2.3 Reanalysis

301   We use the atmospheric reanalysis ERA5 (Hans Hersbach et al., 2020) to evaluate the
302   DeepMIP ensembles performance for the preindustrial control simulation. ERA5 is a
303   comprehensive reanalysis from Copernicus Climate Change Service (C3S) produced by
304   ECMWF and it is based on the Integrated Forecasting System (IFS) Cy41r2 which was
305   operational in 2016. In our study we used monthly averaged data on pressure levels and on single
306   levels (H. Hersbach et al., 2019b, 2019a) from the time period 1991-2020 on a horizontal
307   resolution of approximately 0.25°x0.25°.

308   2.4 Partitioning the meridional heat transport

309   In our study we analyze the total meridional heat transport, and focus on its components,
310   in the atmosphere. We follow the method described in Donohoe et al. (2020). First the MHT is
311   partitioned between the ocean and the atmosphere

312   $$MHT = OHT + AHT \,, \hspace{3cm} (1)$$

313   and the atmospheric transport is further partitioned into contributions from meridional
314   overturning circulation (MOC), stationary eddies (SE) and transient eddies (TE)

315   $$AHT = MOC + SE + TE. \hspace{3cm} (2)$$

316   Furthermore, all parts of Eq. (2) are divided into dry and moist energy transport (Eq. 3),
317   where the moist part consists the transport of energy via latent heat and the dry part consists the
318   transport of potential energy and sensible heat.

319
$$AHT = AHT_{moist} + AHT_{dry}$$

320
$$MOC = MOC_{moist} + MOC_{dry}$$

321
$$SE = SE_{moist} + SE_{dry}$$

322
$$TE = TE_{moist} + TE_{dry} \tag{3}$$

323   The total meridional heat transport at a latitude circle can be calculated with dynamic and
324   energetic approaches, where in the energetic approach the MHT is balanced by the spatial
325   integral of the net radiative deficit at the top of the atmosphere (TOA) and in the dynamic
326   approach MHT is the vertically and zonally integrated net transport of energy. Here we use the
327   energetic approach to calculate MHT (Eq.4)

328
$$MHT(\Phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\Phi} \cos\Phi' \left[ASR(\Phi') - OLR(\Phi') \right] d\Phi', \tag{4}$$

329   where ϕ is the latitude circle, a is the radius of the Earth, ASR is the absorbed solar
330   radiation, OLR is the outgoing longwave radiation. The boundary condition is that the transport
331   has to be zero at the pole, because non-zero values have no physical meaning. To fulfill the
332   boundary conditions at both poles, we need to balance the global budget. For this we assume that
333   the imbalance is spatially uniform, thus the area-weighted global average energy imbalance is
334   subtracted at all latitudes before calculating the integral in Eq. (4).

335   OHT can also be calculated with the energy approach from the surface heat fluxes (SHF)
336   (Eq. 5)

337
$$OHT(\Phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\Phi} \cos\Phi' \left[SHF(\Phi') \right] d\Phi', \tag{5}$$

338   where SHF is positive downward. The above equation is true with the assumption that the
339   ocean is in equilibrium, so the heat storage is negligible. If the ocean is not in an equilibrium
340   state, then Eq. (5) represents the implied OHT, which is the sum of OHT and the spatial integral
341   of the tendency of ocean heat content. The DeepMIP simulations have been required to fulfill
342   different criteria to prove that they reached the equilibrium state. The criteria considered the
343   length of the simulations, the radiation imbalance at the TOA, and the ocean's equilibrium state.
344   All of the included simulations satisfy at least two of the three criteria, with the only exception of
345   CESM at $3xCO_2$, which is still close to both missed criteria, thus all, here considered
346   simulations, have been accepted to be sufficiently equilibrated (Lunt et al., 2021). We consider
347   Eq.(5) defining OHT and that balancing the global radiative budget at the TOA does not largely
348   affect largely the calculation of MHT.

349   After calculating MHT and OHT given Eq. (1) AHT is known as the residual. The direct
350   dynamical calculation of AHT is formulated via the vertically and zonally integrated meridional

351   transport of moist static energy (MSE):

352
$$MSE = c_p T + Lq + gZ$$

353   $$AHT(\Phi) = \frac{2\pi a \cos \Phi}{g} \int_0^{P_s} [\bar{V}] [\overline{MSE}] + [V^* MSE^*] + \overline{[V'^* MSE'^*]} + \overline{[V]'[MSE]'} dp,$$

354   (6)

355   where cp is the specific heat capacity of air at constant pressure, T is temperature, L is the
356   latent heat of vaporization of water, q is the specific humidity, g is the acceleration of gravity, Z
357   is the geopotential height, P_s the surface pressure, V is the meridional velocity. The square
358   brackets [x] denote zonal averages, the overbars $\bar{x}$ denote time averages (monthly means), x*
359   denote zonal anomalies, and x' means time anomalies. In Eq. (6) the first term defines the energy
360   transported via MOC the second is SE, the third is TE, and the last one has been referred as the
361   transient overturning circulation (TOC) (Marshall et al., 2014), which is two orders of
362   magnitudes smaller than MOC at the tropics and the eddy terms at midlatitudes. Thus, we do not
363   try to consider TOC on its own, but handle it together with TE. Note that the calculation of TE
364   and TOC would require high temporal resolution data, which is not available for the DeepMIP
365   simulations, thus we cannot calculate AHT only from Eq. (6), hence we use the residual method
366   via Eq. (1). Nevertheless, the transport via MOC and SE is calculated from Eq. (6) with monthly
367   mean data. The remaining atmospheric transport, which we refer to as TE, is again defined with
368   a residual method. This TE calculation, has been shown to be successful in calculating the
369   partitions from monthly mean data with good accuracy (Donohoe et al., 2020).

370   Regarding the moist and dry partitioning for AHT we define AHT_moist as the latent heat
371   transport at a given latitude, which is the integral of evaporation (E) minus precipitation (P)
372   multiplied by the latent heat of vaporization:

373   $$AHT_{moist}(\Phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\Phi} \cos \Phi' \{L[E(\Phi') - P(\Phi')]\} d\Phi' \ . \qquad (7)$$

374   The dry contribution to AHT is then calculated by subtracting the moist part from the
375   total (Eq. 3). The moist and the dry parts of MOC an SE are calculated via Eq.(6), but MSE has
376   been split into dry, the sensible heat and potential energy (cpT+gZ) and moist part, the latent heat
377   (qL) (Donohoe et al., 2020). The moist and dry contributors to TE can be calculated via the
378   residual method, with the use of Eq. (3) and:

379   $$AHT_{moist} = MOC_{moist} + SE_{moist} + TE_{moist}.$$

380   2.5 Meridional Streamfunction

381   There are several metrics to quantitively analyze the Hadley cell, its edge and its
382   circulation strenght. We choose to use the average meridional streamfunction Ψ (Xian et al.,
383   2021) to quantify its intensity, which is defined as :

384   $$\Psi(p, \Phi) = \frac{2\pi a \cos \Phi}{g} \int_{P_s}^0 [v] dp \ .$$

385   A stronger streamfunction means a stronger Hadley cell circulation.

386   2.6 Monsoon Area

387   The monsoon climate is characterized by seasonal reversal of prevailing surface winds
388   which results in a rainy summer and dry winter. To assess the geological area where monsoon
389   was probably present in the EECO, we use a simple monsoon definition, which is also used in
390   the 6th Assessment Report of IPCC (IPCC, 2021). The global monsoon is defined as the area,
391   where the local annual range of precipitation exceeds 2.5 mm per day (Kitoh et al., 2013). The
392   annual range is defined by the local summer- minus-winter precipitation, i.e. MJJAS minus
393   NDJFM in the Northern Hemisphere and NDJFM minus MJJAS in the Southern Hemisphere.
394   The 2.5 mm per day threshold is defined based on current conditions, which might not hold so
395   well in a warmer world, nevertheless we accept it for our rough estimations. A more detailed
396   analysis of the monsoon systems is to follow this study, where not just such simple indices will
397   be used.

398   **3 Results**

399   3.1 Preindustrial control simulation

400   We start our analysis by evaluating the selected models' representation of present day
401   climate, more precisely the climate of the preindustrial period. To assess the models' results we
402   compare them to transport values calculated from the ERA5 reanalysis from 1991-2020. Note
403   that this comparison is not entirely fair since the models and the reanalysis represent two
404   different climate periods approximately 150 years apart, and in this one and a half century the
405   climate constraints, especially the CO_2 concentration have changed. Nevertheless, both models
406   and reanalysis represent a climate with current topography, continental ice sheets and relatively
407   similar meridional temperature gradient, when compared to our knowledge of EECO's climate.
408   Thus, we accept these discrepancies and focus on the structure of the transport processes, and not
409   on the quantitative amounts.

410   The meridional heat transport and its partitions calculated from the DeepMIP models and
411   the ERA5 reanalysis are shown in Figure 1. Overall, there is good agreement between the mean
412   of the model ensemble and the reanalysis. The values and distributions of the MHT and its
413   components fit well also to previous studies which are based on observations and reanalysis
414   (Donohoe et al., 2020; Masuda, 1988).
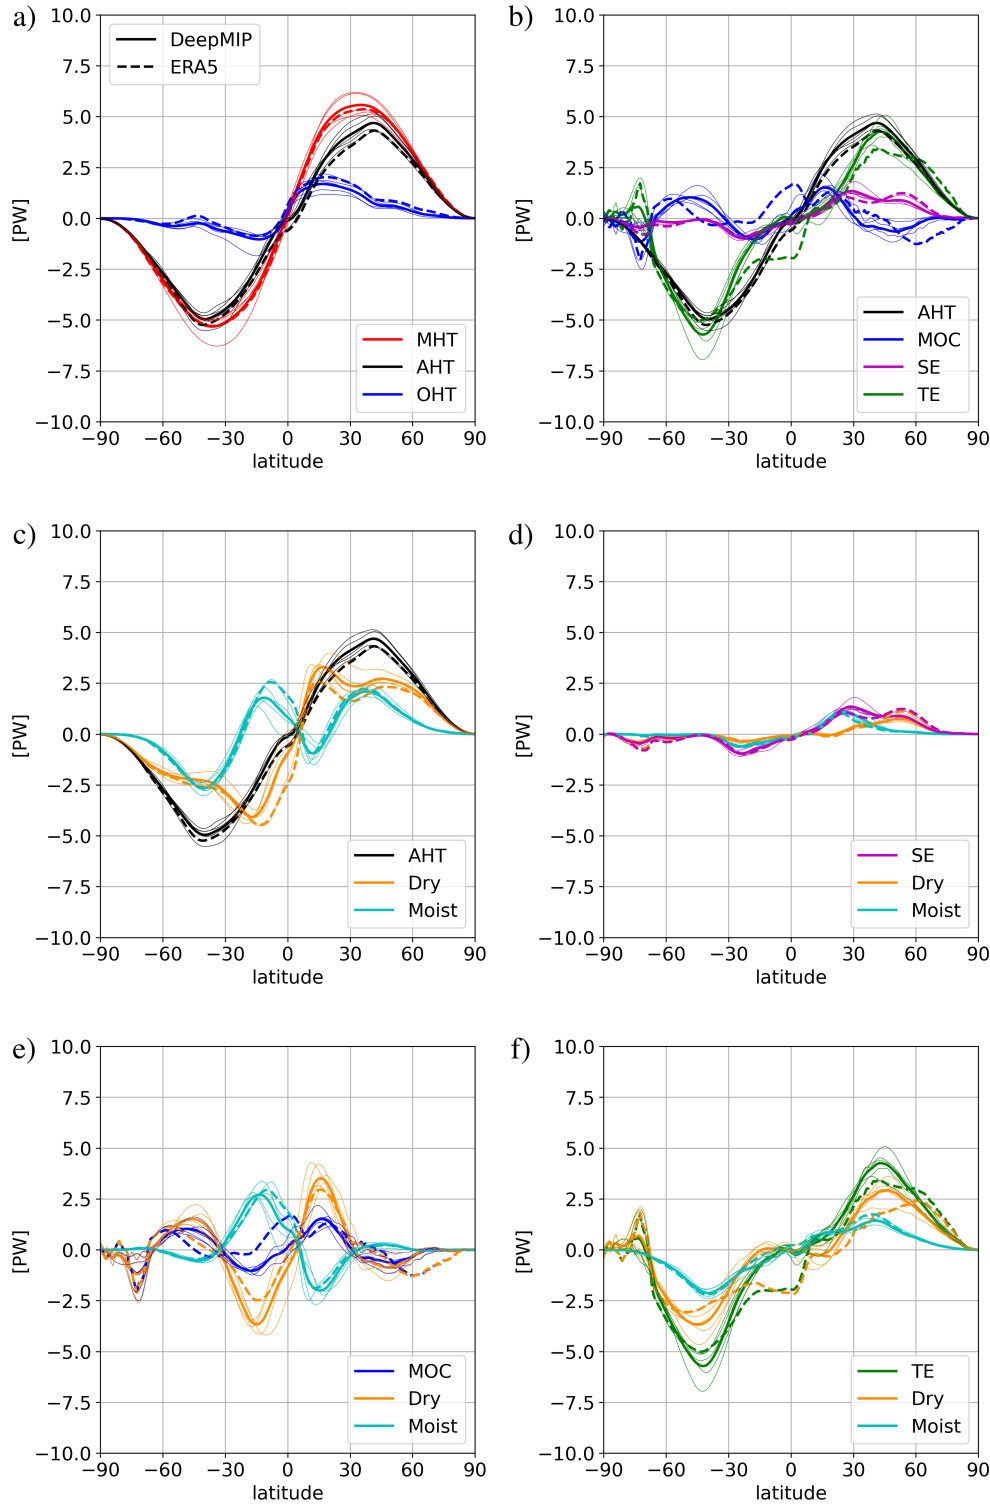

415   MHT reaches maximum of above 5 PW at around 40° both South and North. The ocean
416   transports more heat than the atmosphere in a narrow tropical belt (0-10 °N), outside of which
417   the atmospheric heat transport dominates (Figure 1a). The reanalysis is within the spread of the
418   DeepMIP ensemble. The ensemble mean fits the reanalysis better over the southern hemisphere
419   than over the northern, where the models transport more via the atmosphere and less via the
420   ocean. These two compensate each other resulting in a good fit for the total MHT.

421   The atmospheric transport partitioned into latent heat and dry static energy transport
422   (Figure 1c) shows that the two have similar order of magnitude, but the dry static energy
423   transport is at all latitudes poleward, while the latent heat transport is equatorward in the tropics
424   and poleward at the rest of the latitudes.

425   Partitioning of the atmospheric heat transport into meridional overturning circulation,

426   stationary, and transient eddies shows that transport is (a) mainly in transient eddies in the
427   midlatitudes, i.e. in extratropical cyclones, and (b) dominantly by meridional overturning
428   circulation, i.e., by the Hadley cells, in the tropics (Figure 1b). The tropical belt is where some
429   differences between the models and the reanalysis arises, namely over the Southern Hemisphere
430   the reanalysis shows more northward transport via meridional overturning circulation, MOC, and
431   more southward transport via transient eddies, TE. Since these two mechanisms act in the
432   different direction, the AHT does not show large differences between the reanalysis and the
433   ensemble mean. The separation of the MOC into its dry and moist parts (Figure 1e) reflects the
434   poleward transport of potential and sensible heat in the upper part of the Hadley cell and the
435   equatorward latent heat transport in the lower part of the Hadley cell. The transport of the two
436   parts do not balance out each other resulting in a net poleward energy transport. Stationary
437   eddies show importance in the poleward latent heat transport around 30° in both hemispheres,
438   representing the monsoon systems (Figure 1d). Stationary eddies also transport dry static energy
439   to the northern midlatitudes, mainly during winter, representing planetary waves (Masuda,
440   1988). Extratropical cyclones transport heat in both, the moist and dry form (Figure 1b and f).

Figure 1. Annual meridional heat transport and its different parts in the preindustrial control simulations of the 5 DeepMIP ensemble members and the ERA5 reanalysis. Bold lines representing the ensemble mean thin lines representing each model and dashed lines are calculated from ERA5 (1991-2020) reanalysis. The partitions of MHT are (a) Meridional Heat Transport, divided between atmospheric (AHT) and oceanic (OHT) part, (b) atmospheric
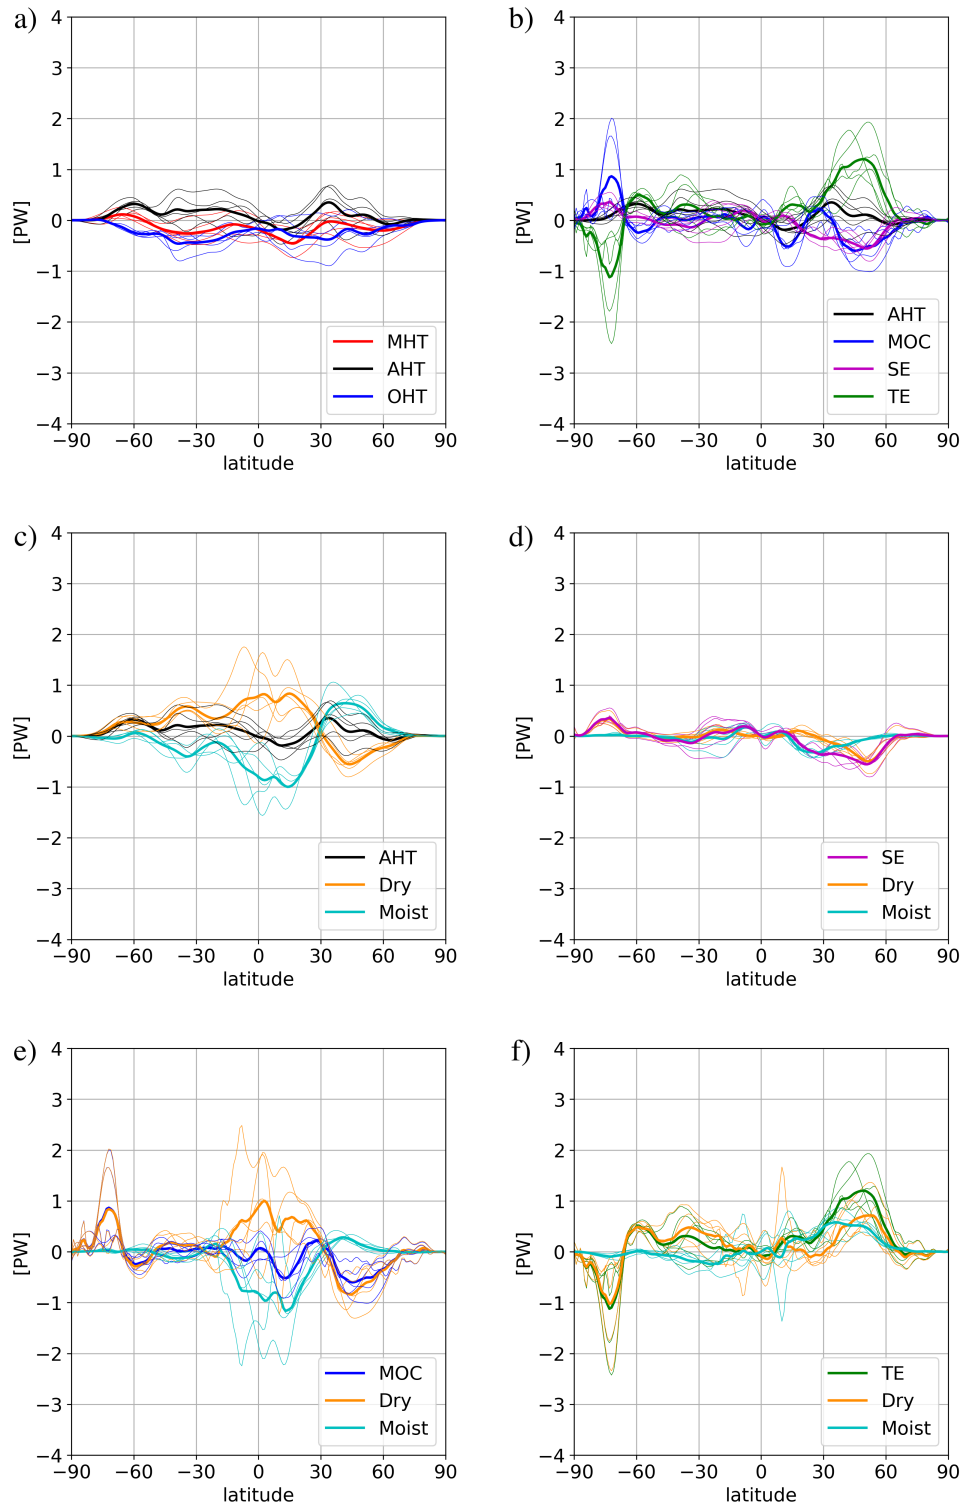

447   transport divided into Meridional Overturning Circulation (MOC), Stationary Eddies (SE) and
448   Transient Eddies (TE), (c) atmospheric transport divided to dry and moist parts, (d) atmospheric
449   transport via SE and its dry and moist parts, (e) atmospheric transport via MOC and its dry and
450   moist parts, and (f) atmospheric transport via TE and its dry and moist parts.

451   3.2 Effect of the Non-CO_2 forcing on the Eocene MHT

452   The Eocene $1xCO_2$ simulations, i.e., with non-CO_2 forcing because of changes in
453   paleogeography and vegetation or the lack of continental ice sheets, are 3-5 °C warmer than the
454   preindustrial simulations (Lunt et al., 2021). Figure 2 shows the MHT differences between the
455   Eocene $1xCO_2$ and the preindustrial control simulation. There is more southward MHT in the
456      $1xCO_2$ simulation than in the preindustrial one, which is mainly due to an increase in the oceanic
457   southward heat transport (Figure 2a). This results in smaller poleward MHT in the Northern
458   Hemisphere but larger in the Southern Hemisphere during the Eocene. In other words, due to the
459   Eocene boundary conditions the atmospheric poleward transport increases and the ocean
460   transport decreases in the Northern Hemisphere and vice versa in the Southern Hemisphere.

461   The change in atmospheric dry and moist transport is also asymmetric. North from the
462   Tropic of Cancer (30°N) more latent heat is transported northward and south from it more latent
463   heat is transported southward in the Eocene than in the preindustrial climate. The dry static heat
464   transport changes show the opposite sign. When taking into consideration the direction of
465   transport (see Figure 1c), this means that over the Northern Hemisphere there is more moisture
466   transport equatorward in the tropics and more poleward transport at midlatitudes, while the dry
467   static energy transport compensates these changes, with more poleward transport at the tropics
468   and less at higher latitudes (Figure 2c). On the other hand, over the Southern Hemisphere the
469   tropical equatorward latent heat transport decreases and the extratropical poleward latent heat
470   transport increases. The poleward dry static energy transport decreases at all southern latitudes.
471   These together lead to a net increase (decrease) in atmospheric poleward transport in the
472   Northern (Southern) Hemisphere, which as mentioned above is overcompensated by the ocean.
473   An increase in poleward latent heat transport also has an important role in polar amplification.

474   The most prominent atmospheric change is the increased heat transport by transient
475   eddies between 30°N-60°N and 60°S-90°S (Figure 2b). These represent heat transport by
476   extratropical cyclones, thus cyclones are more frequent and/or more intense in the Eocene
477   simulations. To quantify the number of cyclones and their features, more frequent than monthly
478   model output would be needed. The increased transient eddies transport is mostly compensated
479   by stationary eddies and meridional overturning circulation transports (Figure 2b). There is also a
480   decrease in the northern hemisphere monsoonal transport (Figure 2d). The Hadley circulation
481   also shows an asymmetric shift, with more energy being overturned in the northern cell, and less
482   in the southern one, while the net poleward MOC energy transport stays close to the control
483   simulation (Figure 2e).

Figure 2. Meridional Heat Transport and its parts, same as Figure 1, but showing the differences between the 1xCO_2 Eocene and the preindustrial control simulations.
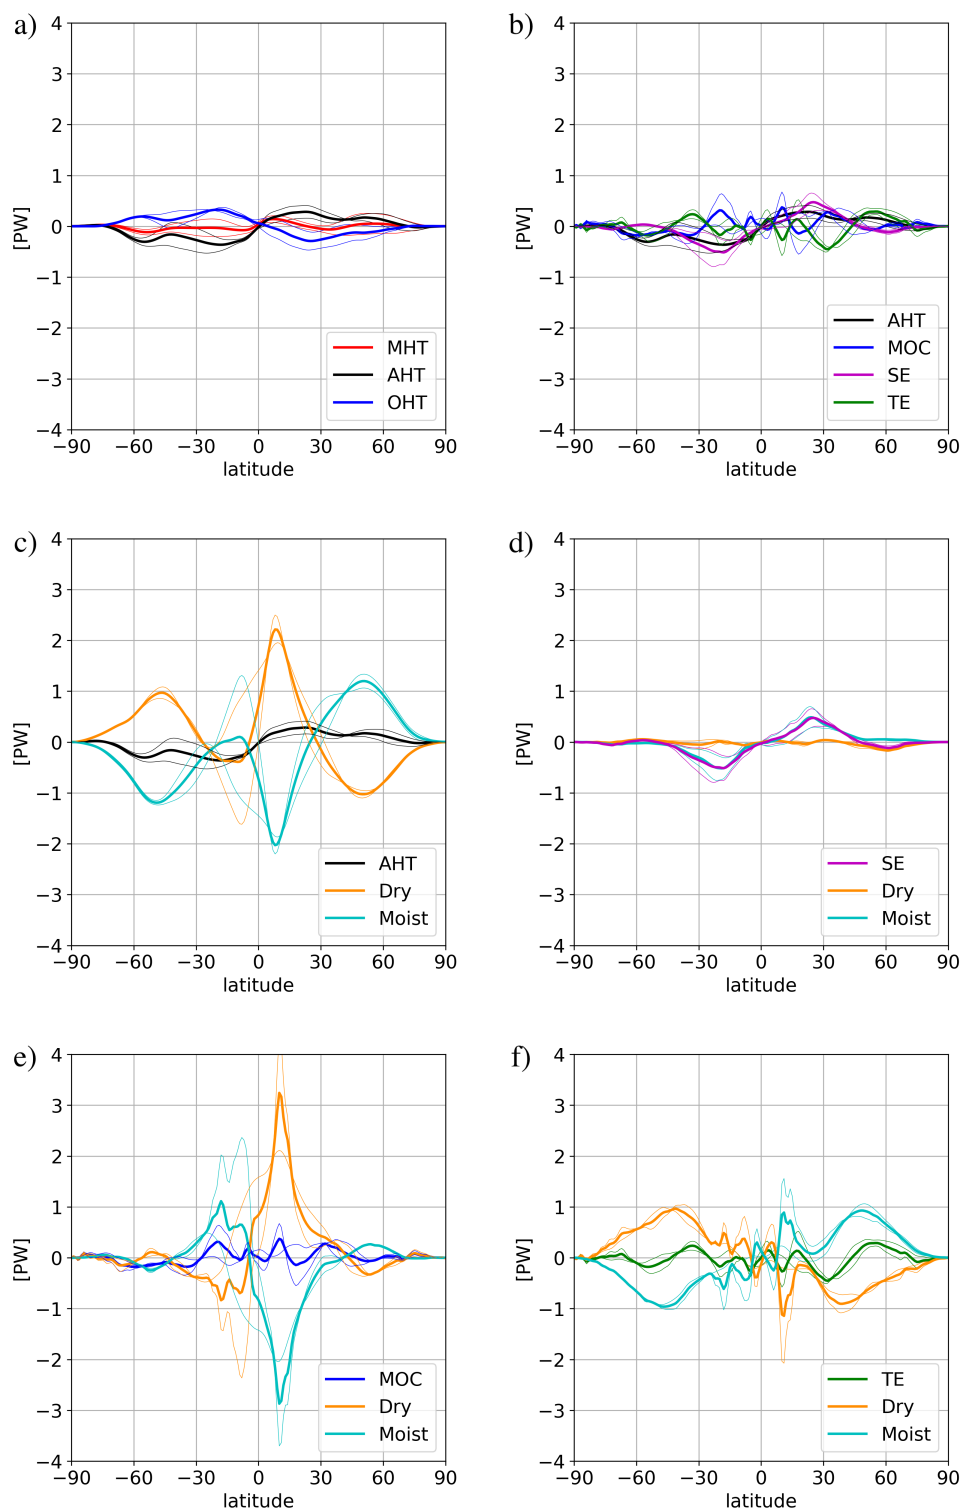

488   3.3 Effect of the CO_2 forcing on the Eocene MHT

489   The effect of higher CO_2 concentrations on early Eocene transport processes is studied by
490   quantifying the changes between the $3xCO_2$ and $6xCO_2$ simulations relative to the $1xCO_2$
491   simulation (Figure 3 and 4). We compare the $6xCO_2$ simulation also to the $1xCO_2$ one to display
492   the intensification of the signal due to CO_2 rise. Our choosen DeepMIP ensemble has five
493   models available with $3xCO_2$ simulations and only two with $6xCO_2$ simulations (CESM &
494   GFDL, see Tab. 1). The two latter simulations are shown to be the most successful in
495   representing the global mean surface temperature, global mean SST and global meridional SST
496   gradient when compared to proxy data (Lunt et al., 2021) and thus we trust this small ensemble
497   is still representative.

498   When comparing the changes relative to the equator, we see mostly symmetric changes,
499   thus the effect of CO_2 rise is global and influences both hemispheres in a similar way. For the
500    $3xCO_2$ simulation we find an increase in poleward MHT compared to the $1xCO_2$ simulation,
501   which mainly results from the atmosphere (Figure 3a), while at the $6xCO_2$ simulation the MHT
502   is fluctuating around zero (Figure 4a). In the latter case anomalies in the atmospheric and ocean
503   heat transport counteract one another, i.e., the Bjerknes compensation is present. The differences
504   between the two figures, and hence CO_2 concentrations, can also arise from the different set of
505   models used for the ensemble mean. Especially, since GFDL presents a non-linear behavior, and
506   from $4xCO_2$ to $6xCO_2$ concentration a slight decrease in the full MHT is found over the Northern
507   Hemisphere. Its magnitude is smaller than the CESM signal, thus the ensemble mean still
508   indicates a positive poleward transport change. Nevertheless, both at $3xCO_2$ and $6xCO_2$
509   concentration, the poleward atmospheric heat transport increases and ocean's heat transport
510   decreases or stays close to the $1xCO_2$ value in the ensemble mean. Polar amplification is also
511   represented via the increased latent heat transport from the subtropics towards the poles,
512   compensated by the dry static heat transport (Figure 3c and 4c). Regarding the different physical
513   processes in the atmosphere, we see similar changes in both $3xCO_2$ and $6xCO_2$ simulations.
514   (Figure 3b and 4b). At the tropics the change in the net meridional overturning circulation
515   transport is close to zero, but the dry static and latent heat energy transport of the Hadley cell
516   increases more so at the northern cell than at the south (Figure 3e and 4e). The subtropics, are
517   mostly defined by the increased poleward transport of moist stationary eddies, namely the
518   transport of the monsoon systems, more in the $6xCO2$ than in the $3xCO_2$ simulation (Figure 3d
519   and 4d). At midlatitudes the poleward transport of transient eddies increases slightly, especially
520   in the $6xCO_2$ simulations (Figure 4f), but the magnitude of change is smaller than, what the non-
521   CO_2 constraints caused in the $1xCO_2$ simulations (see Figure 2f).

522

523

524 **Figure 3**. Meridional Heat Transport and its parts, same as Figure 2, but showing the differences
525 between the 3xCO$_2$ and the 1xCO$_2$ paleo simulation.

526

527

Figure 4. Meridional Heat Transport and its parts, same as Figure 3, but showing the differences between the $6xCO_2$ and the $1xCO_2$ paleo simulation. The ensemble here consists only two models: CESM, GFDL.
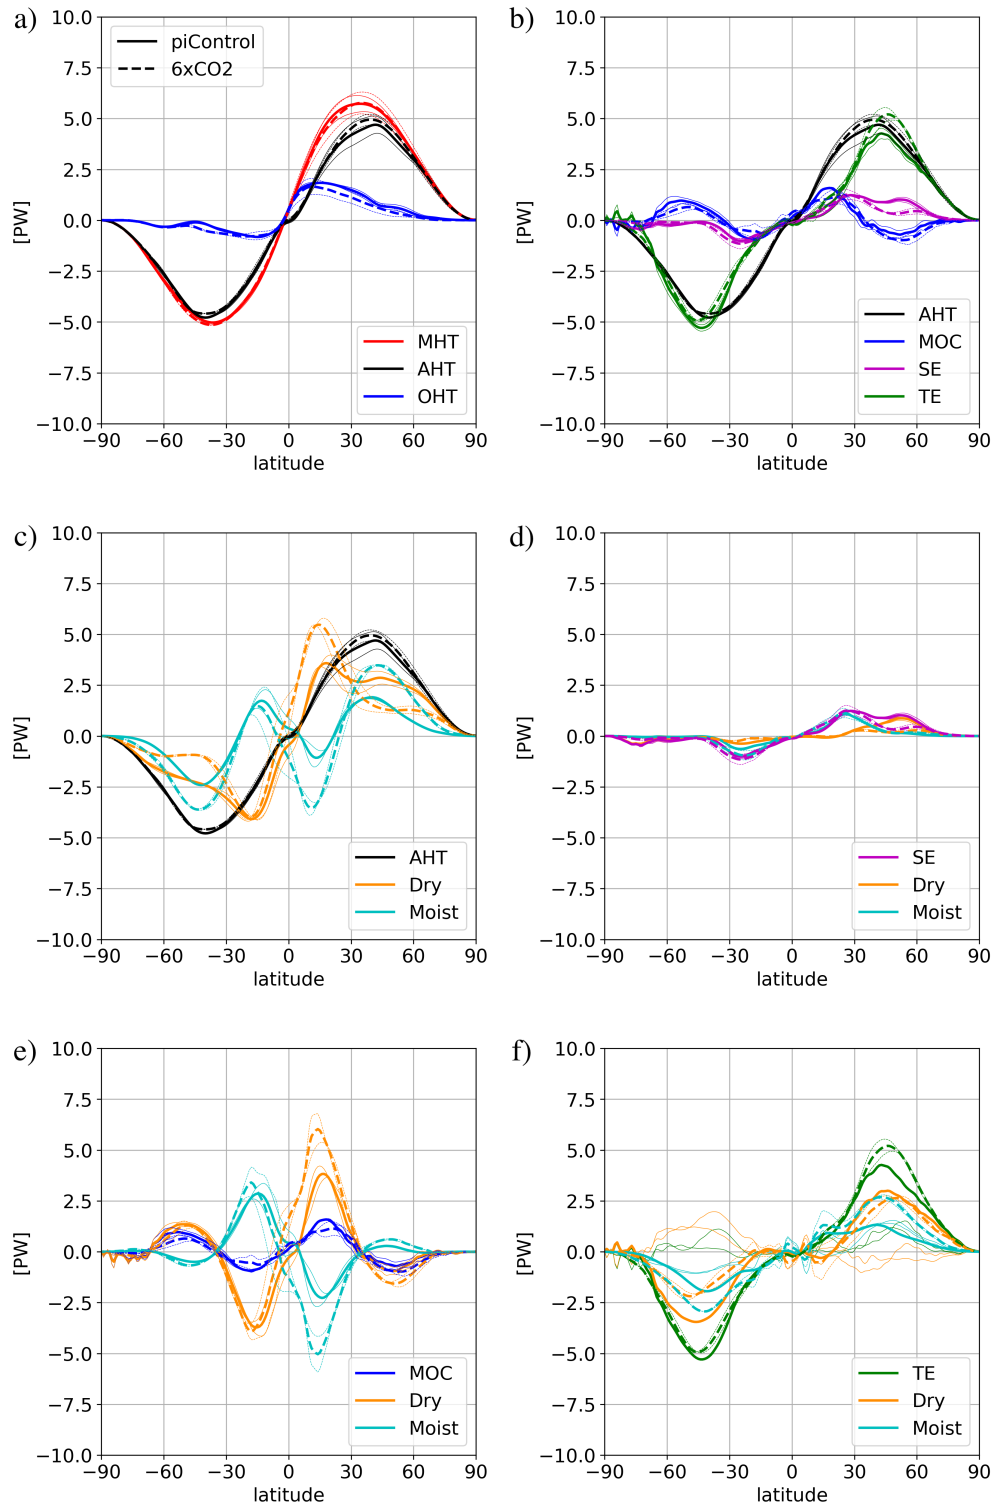

531

532   3.4 Effect of the total forcing on the Eocene MHT

533   Finally, we investigate the overall heat transport changes between the simulated
534   preindustrial and most-likely Eocene climate states. This is important as it is the relevant change
535   when comparing Eocene proxy data to present day conditions, and because the individual
536   changes due to the CO_2 and the non-CO_2 constrains are potentially nonlinear and can counteract
537   each other.

538   In total meridional heat transport, we see more changes compared to the present day
539   climate in the Northern Hemisphere, where the atmosphere transports more energy while the
540   ocean compensates this with less transport (Figure 5a). There is an increase of latent heat
541   transport toward the polar regions at both hemispheres in the EECO climate, which is
542   compensated by the decrease in dry static energy transport at the midlatitudes (Figure 5c). In the
543   tropics the net transport via meridional overturning circulation stays close to the preindustrial
544   values, but the dry (poleward) and moist (equatorward) energy transport increases in the Hadley
545   cell, especially in the northern cell (Figure 5e). In the southern subtropics the EECO simulations
546   show slightly more latent heat transport via stationary eddies (Figure 5d). This means that the
547   monsoon systems in the Southern Hemisphere transported more energy during the EECO.
548   Nevertheless, it has been shown in the previous two subsections that the monsoon in the
549   Northern Hemisphere also changed, but with opposite signs due to the respective CO_2 and non-
550   CO_2 forcings. Thus, the overall monsoonal transport changes in the Northern Hemisphere are
551   small. At the midlatitudes, especially in the Northern Hemisphere more energy is transported via
552   transient eddies (cyclones) during the Eocene, which is again compensated by less transport via
553   stationary eddies (Figure 5b,d,and e). In the Southern Hemisphere we find slightly less transient
554   eddy transport in the EECO than in the preindustrial simulations.

555

Figure 5. Meridional Heat Transport and its parts, same as Figure 1, but showing the preindustrial control (solid lines) and 6xCO2 (dashed lines) simulation results. The included models are: CESM, GFDL.

561   **4 Discussion**

562   The analysis of the different transport processes identified those large scale circulation
563   patterns, which are either effected by the changes in the paleo set up or by the changes in the
564   CO_2 concentration. These, heading from the tropics to the pole, are the Hadley cell, the monsoon
565   and the mid-latitude cyclones. In this section we discuss the changes in these large scale patterns
566   in more detail.

567   4.1 Hadley Cell

568   We found that due to both the CO_2 and non-CO_2 constraints more dry static energy and
569   latent heat is turned around by the Hadley cells. Since all these simulations have a generally
570   warmer climate than the control simulation it means that part of the surplus of energy compared
571   to the preindustrial simulation, is coming from the higher water holding capacity of the warmer
572   atmosphere. Both the CO_2 and non-CO_2 constraints cause a larger change in the Northern Hadley
573   cell. When using the streamfunction for investigation of the Hadley circulation in the high CO_2
574   simulations, all models show a weakening intensity of the Southern cell and a shift of the
575   Northern cell towards south. The intensity of the Northern cell is strengthening in HadCM3,
576   MIROC, and COSMOS, while CESM and GFDL show a slight weakening (see Table 2). Figure
577   6 shows this exemplarily for the simulation GFDL. The southern cell is decreasing in intensity
578   with the CO_2 rise, while the northern cell is expanding, mostly southward, and slightly increases
579   in intensity. The southward expansion of the northern cell can be partially explained by the
580   paleogeography. In the Eocene less continental land areas were located in the northern tropical
581   belt. This could lead to a relative southward shift of the Intertropical Convergence Zone (ITCZ),
582   given that during the summer half year the ITCZ travels poleward mostly over the continental
583   areas. Nevertheless, the reason for the hemispheric asymmetry in overturned energy, intensity
584   and position between the northern and southern Hadley cell due to CO_2 constraints is not entirely
585   clear. These findings are in line with what we see in the modern day changing, warming climate.
586   The 6th IPCC report states that a widening of the Hadley cells has been observed in the last
587   decades, together with a strengthening of their circulation, especially in the Northern Hemisphere
588   (Gulev et al., 2021).

589

590   **Table 2**

597   4.2 Monsoon

598   In the subtropics the transport via moist stationary eddies represents the heat transport by
599   monsoon systems. The analysis of the non-CO_2 effects showed a decrease in their transport in the
600   Northern Hemisphere and the CO_2 effects analysis showed an increase in transport with the CO_2
601   rise. Thus, we investigated the monsoon area to better evaluate these changes. The monsoon
602   area is defined by a precipitation index in all simulations.

603   In Figure 7 the monsoon areas are plotted from the CESM preindustrial 1x, 3x and $6xCO_2$
604   concentration simulation. Paleogeography plays an important role in defining monsoon areas as
605   is shown by the smaller monsoon area in the early Eocene set-up than in the preindustrial. From
606   the preindustrial to the $1xCO_2$ simulations, the percentage of monsoon areas decreases in all
607   models (see Table 3). The mean of the ensemble shows that in the preindustrial simulations the
608   monsoon covers 18.7% of the globe, while in the $1xCO_2$ this area is reduced to 14.8%. This
609   correlates well with the slight decrease in the transport of moist stationary eddies in the
610   subtropics (Fig. 2d). From the 1x to the 3x and to the $6xCO_2$ simulations (for CESM), the
611   monsoon area increases with higher CO_2 values (Figure 7). This also correlates well with the
612   results seen in the transport figures, where there is an increase in moist stationary eddy transport
613   in the subtropics (Figure 3d and 4d). The only exception from the increase of monsoon area with
614   CO_2 rise, is GFDL with a decrease in monsoon area from the 3x to the $6xCO_2$ simulation.

615   When comparing the preindustrial climate to the EECO, namely the preindustrial

616   simulations to the 6xCO₂ simulations for CESM and GDFL simulations, we see that the effect of
617   the non-CO₂ constraints (smaller monsoon area in the Eocene) and the effect of the CO₂ forcing
618   (higher water holding capacity of the warmer atmosphere) compensate each other in terms of the
619   energy being transported. This agrees well with the findings of Licht et al. (2014), who
620   investigated proxy data from Asia in the late Eocene (gastropod shells and mammal teeth from
621   Myanmar, and aeolian dust deposition in northwest China) and found monsoon like patterns in
622   rainfall and wind. They also concluded that the enhanced greenhouse gas concentrations
623   compensated the negative effect of lower Tibetan relief on precipitation, which reduces the East
624   Asian monsoon strength (Tang et al., 2013). In summary, when comparing present and EECO
625   monsoon systems from the energetic point of view, there is no large difference (Figure 5d),
626   nevertheless the reason for this is due to compensating mechanisms. Note that this does not
627   indicate that there is no significant change in monsoon precipitation intensity.

628

636

637   4.3 Midlatitude cyclones

638   We found that in the paleo set up even without the CO$_2$ increase, more energy is being
639   transported via midlatitude cyclones especially in the Northern Hemisphere (Figure 2b). This can
640   be explained by an increase in semi-permanent low pressure systems, in other name centers of
641   action, in the Eocene simulations. In Figure 8 the sea level pressure anomalies are representing
642   these centers of action. In the Northern Hemisphere in the preindustrial simulation one can
643   identify two main low pressure systems during winter (Figure 8a), the Icelandic and the Aleutian
644   lows, while in the Eocene even four low pressure centers can be identified. We call these the
645   Icelandic, the Aleutian, the Gulf of Alaska and the Eurasian Low (Figure 8c).

646   The development of these semi-permanent pressure features is connected to the thermal
647   contrast between the ocean and the continent during winter, due to the different heat capacity of
648   land and sea. This also explains why the semi-permanent pressure systems develop differently in
649   the paleo set up. In the Eocene world there was a wider Pacific basin and a narrower Atlantic
650   basin together with the existence of the Turgai Sea or West Siberian Sea, an epicontinental sea
651   separating Europe from Asia. The existence of the West Siberian Sea, which is located in the
652   northern midlatitudes, lead, in the models, to the development of an Eurasian Low pressure
653   system that is not in present in the modern times. The wider Pacific basin and the presence of the
654   Bering land bridge lead, in the models, to a split in the Aleutian Low, so in the Eocene both an
655   Aleutian Low and a Gulf of Alaska Low are present in the simulations. In the Southern
656   Hemisphere the position of the Antarctic continent did not change much and, thus, the pressure
657   systems in the models developed similarly as in the present climate (Figure 8 b and d).

658   We hypothesize that the increase in the energy transport via transient eddies in the
659   paleosimulations are due to the increase in cyclonic activity due to more semi-permanent low
660   pressure systems over the northern midlatitudes. This can mean more and/or deeper cyclones
661   than in the present climate. To quantitatively assess this, the model output in our study with the
662   monthly temporal resolution is insufficient.

663

5 Conclusions

In this study we calculated and analyzed the meridional heat transport and its partition in the atmosphere in climate model simulations of the preindustrial and the Early Eocene Climatic Optimum (EECO). We used simulations from five climate models (CESM, COSMOS, GFDL, HadCM3, and MIROC) provided by the DeepMIP community. The transport values are calculated from monthly mean data, and we distinguish between the different physical mechanisms, which transport energy in the atmosphere. The impacts of the non-CO_2 related conditions (paleogeography, vegetation, no continental ice sheets) and the CO_2 concentration forcing on the transport processes are calculated first separately, and then in combination, to allow a full comparison of heat transport in the preindustrial and early Eocene. The transport processes via the Hadley cell, the monsoon systems and the midlatitude cyclones are analyzed in more detail as these large-scale circulation patterns are identified as being different in the EECO compared to present day.

Our first research question investigates the DeepMIP models' skill in capturing the characteristics of transport processes in the preindustrial simulations (section 4.1). Overall, the DeepMIP ensemble mean and the reanalysis transport values show good agreement. Only the Southern Hemispheric tropical MOC transport shows marked differences, but due to two compensating mechanisms the overall atmospheric heat transport is still similar between the reanalysis and the multi-model mean.

The impacts of non-CO_2 constraints (paleogeography, vegetation, no continental ice sheet) on the different transport processes show hemispheric asymmetry. In the 1xCO₂ Eocene simulations the total poleward MHT is smaller in the Northern Hemisphere but larger in the

688   Southern Hemisphere. This is mainly due to the same change in oceanic transport. This shift in
689   oceanic transport towards the South Pole is in line with the strong Southern Hemisphere-driven
690   oceanic overturning circulation of the Eocene, found in the DeepMIP models (Zhang et al.
691   (2022). Considering the different physical processes most notable is the extra heat transport by
692   transient eddies in the midlatitudes, which is compensated by a loss in energy transport via
693   stationary eddies. The increase in cyclonic heat transport is explained by changes in
694   paleogeography. The existence of an extra epicontinental sea at the north midlatitudes, with
695   possible high land-sea thermal contrast, results in a semi-permanent pressure system, which
696   impacts the transient eddies at the midlatitudes. Also, the wide Pacific basin results in a split in
697   the Aleutian Low. Thus, in the end during the Eocene winter there were probably 4 semi-
698   permanent low pressure systems present at the northern midlatitudes as opposed to the only two
699   in present day climate. The increase in semi-permanent lows likely results in an increase in
700   cyclone numbers as well, but to quantify this, one needs high temporal resolution output from the
701   models. A decrease in North Hemispheric monsoon latent heat transport, is also linked to the
702   change in topography, since the location of land areas highly determines the monsoon area.

703   Transport changes, which are solely due to CO_2 increases in the 3x and 6x CO_2 EECO
704   simulations, are especially relevant to better understand and predict changes under future climate
705   change. We find that with increasing CO_2 concentrations, the atmosphere transports more heat
706   poleward, while the ocean transports the same amount or less. The results also show that the
707   Hadley cell overturns more heat on the northern side of the Equator more than on the southern
708   side. Also, monsoon systems transport more latent heat from the subtropics to the higher
709   latitudes. This indicates that with CO_2 rise the hydrological cycle intensifies. This agrees well
710   with what have been found in our current changing climate. At the end of the 20th century the
711   Hadley circulation is shown to be strengthening particularly in the Northern Hemisphere, while
712   the global monsoon precipitation shows a positive trend in the Northern Hemisphere (Gulev et
713   al., 2021).

714   Our third research question considers the total change between the preindustrial control
715   and EECO simulations, and asks which physical processes are affected the most. In our results
716   we see more changes in the Northern Hemisphere, where the atmosphere transports more heat
717   poleward while the ocean compensates this with less poleward heat transport. We found an
718   increase in latent heat transport towards the polar regions in both hemispheres midlatitudes in the
719   EECO climate, and a decrease in poleward dry static energy transport, same results as
720   Heinemann et al. (2009). The increase in latent heat transport is connected to the intense polar
721   amplification of the EECO world. From the effected large scale circulation patterns, the Hadley
722   cell changes both under the CO_2 and non-CO_2 constraints, with an asymmetric shift. More
723   energy is being overturned in the northern cell, and less in the southern one, while the net
724   poleward MOC heat transport stays close to the control simulation. Monsoon systems are also
725   affected by both the non-CO_2 and CO_2 constraint, but in an opposite way. We found smaller
726   monsoon areas in the Eocene, due to the different topography, while at a higher CO_2
727   concentration, the warmer atmosphere's higher water holding capacity means that more heat is
728   transported poleward by the monsoons. At the midlatitudes cyclones' heat transport increase
729   mainly in the Northern Hemisphere, due to the before mentioned topography differences.

730   In summary we found that transport processes indicate a more intense hydrological cycle
731   and also polar amplification in the warmer EECO compared to the present-day climate. We
732   identified which processes are affected by the Eocene boundary conditions and which are

sensitive to the CO_2 increase. The different boundary conditions cause more southward transport in the ocean which is only partially compensated by the atmosphere. The Eocene set up increases the heat transport of northern midlatitude cyclones and decreases the global monsoon area. The CO_2 increase, on the other hand causes an increase in poleward atmospheric heat transport. Regarding the large scale circulation patterns the CO_2 increase results in an increase in the latent heat transport of monsoon systems and more overturning heat in the Hadley circulation, although the net poleward transport of the Hadley cells is stable. Nevertheless, there is an asymmetry between the northern and southern Hadley cell, with larger changes in the northern cell. A more detailed analysis of the largescale circulation patterns of the Eocene climate, in higher temporal and spatial resolution model results, and their comparison to proxy data, is the focus of our further research.

Open Research
